### Abstract

Osteomyelitis is an inflammatory bone disease caused by an infecting microorganism leading to a gradual bone loss. Due to the difficulty in studying osteomyelitis directly in patients, animal models allow researchers to investigate the pathogenesis of the infection and the development of novel prophylactic, anti-inflammatory and antimicrobial treatment strategies. This review is specifically focused on the *in vivo* mouse osteomyelitis studies available in literature. Thus, a systematic search on Web of Science and PubMed was conducted using the query “(infection) AND (mice OR mouse OR murine) AND (model OR models) AND (arthroplasty OR fracture OR (internal fixator) OR (internal fixation OR prosthesis OR implant OR osteomyelitis)”. After critical assessment of the studies according to the inclusion and exclusion criteria, 135 studies were included in the detailed analysis. Based on the model characteristics, the studies were classified into five subject groups: haematogenous osteomyelitis, post-traumatic osteomyelitis, bone-implant-related infection, peri-prosthetic joint infection, fracture-related infection. In addition, the characteristics of the mice used, such as inbred strain, age or gender, the characteristics of the pathogens used, the inoculation methods, the type of anaesthesia and analgesia used during surgery and the procedures for evaluating the pathogenicity of the infecting micro-organism were described. Overall, the mouse is an excellent first step *in vivo* model to study the pathogenesis, inflammation and healing process of osteomyelitis and to evaluate novel prophylaxis and treatment strategies.

**Keywords:** Osteomyelitis, *in vivo*, model, mouse, staphylococci, bone, infection.

## Introduction

### General introduction of osteomyelitis

Osteomyelitis is an inflammatory bone disease caused by an infecting microorganism leading to a gradual bone loss (Kavanagh *et al.*, 2018). The disease can affect a localised bone section or several parts such as cortex, periosteum and even the surrounding soft tissue. These infections can be caused by a contamination through the bloodstream (known as haematogenous infections), by direct seeding of an open fracture related to trauma or surgery or by a contiguous spread from nearby tissue or a prosthetic device (Kavanagh *et al.*, 2018; Lew and Waldvogel, 2004; Zimmerli and Trampuz, 2011). In fact, the main risk factors associated with osteomyelitis are trauma, orthopaedic devices and diabetic foot infection (Berendt *et al.*, 2008).

### Pathophysiology of the disease

Osteomyelitis begins with the bacterial attachment and subsequent biofilm formation on the bone tissue and/or orthopaedic device. Biofilms consist of a community of bacteria attached to a biological or inert surface that are embedded in a matrix of exopolysaccharide, protein and extracellular DNA (Crabbé *et al.*, 2019). The biofilm structure provides an increased tolerance to antibiotics and immune defences, for instance, due to the presence of bacterial phenotypes with low metabolic activity and SCV (Crabbé *et al.*, 2019).

Osteomyelitis is mainly caused by staphylococci, especially by *S. aureus* and *S. epidermidis*, but can also be caused by other Gram-positive pathogens such as streptococci, by Gram-negative pathogens such

as *P. aeruginosa* and even by a mixture of pathogens (Bernthal *et al.*, 2010; Horst *et al.*, 2012; Inzana *et al.*, 2015b). Furthermore, bacterial infections can find other ways to persist despite treatment (Kavanagh *et al.*, 2018). For example, staphylococci can survive intracellularly in human cells such as macrophages, osteoblasts or even osteocytes causing a chronic persistent osteomyelitis extremely difficult to treat (Boelens *et al.*, 2000; Ellington *et al.*, 2006; Valour *et al.*, 2015; Yang *et al.*, 2018). *S. aureus* can also form SACs, small but highly persistent microcolonies in the bone and soft tissue (Guggenberger *et al.*, 2012; Hofstee *et al.*, 2020; Tuchscherer *et al.*, 2017), and can hide in canaliculi within the bone, out of reach of phagocytic cells (de Mesy Bentley *et al.*, 2017). In addition, the worldwide increase in antibiotic resistance leaves fewer treatment options available (O'Neill, 2014). Consequently, patients require prolonged antibiotic treatment and longer hospitalisation and re-operation, resulting in longer disability and in a dramatic clinical and economic burden for the society. Therefore, it is crucial to develop new prevention, diagnosis and treatment strategies for osteomyelitis (Masters *et al.*, 2019; Moriarty *et al.*, 2016).

### Clinical translation and the need for animal models

Novel strategies for prevention, diagnosis and treatment should be properly evaluated to ensure their effectiveness before use in patients. However, the diverse incidence rate of osteomyelitis ranging from 1 to 30 %, depending on the clinical situation and presence of a device (Metsemakers *et al.*, 2015), the diversity in the anatomical locations affected and the wide range of patients age make it difficult to study the disease within the human population (Lazzarini *et al.*, 2006). Moreover, osteomyelitis can be caused by a broad variety of microorganisms, which may necessitate specific treatment for each pathogen (Arciola *et al.*, 2005b).

To overcome these obstacles, animal models have been developed to study the pathology and pathogenesis of osteomyelitis and the efficacy of prophylactic and treatment regimes. These animal

**Fig. 1.** Number of studies using mouse osteomyelitis models per year between 1991 and 2020. The number of mouse osteomyelitis models steadily increased from 2010 to 2020.

models should meet specific features to most accurately model the clinical situation in patients, such as a similar bone anatomy, gender influence or susceptibility to infection (Wancket, 2015). Therefore, only research conducted with well-established animal models will contribute to a better understanding of the pathogenesis of the disease and will advance the progress of novel preventive and treatment strategies towards the clinic (Coenye *et al.*, 2018). Although different animal species such as sheep, rabbit, dog and rats have been used for this purpose, the use of mouse models to study osteomyelitis has rapidly increased during the last decade (Fig. 1; Reizner *et al.*, 2014).

### Mouse models: advantages and limitations

Mouse models for osteomyelitis gained popularity particularly with the unravelling of the mouse genome by the Mouse Genome Sequencing Consortium in 2002 (Mouse Genome Sequencing Consortium *et al.*, 2002). The general advantages of mice as models for osteomyelitis studies are their reproducibility (*i.d.* development of the infection within the mouse strain and availability of the mouse strains to reproduce and continue an experimental approach), their bone physiological and structural similarity to humans, the diversity of genetic and molecular tools available to study them and their relatively low costs. This enables extensive experimental designs, tailored to solve a

wide variety of research questions. Furthermore, the mouse has a relatively short life cycle, providing the advantage of a rapid development of the pathological features of osteomyelitis.

Mouse bone is similar in its physiology and structure to human bone, with the presence of trabecular and cortical bone and with similar cell types. However, mice lack a haversian system (osteon) but instead use resorption cavities for bone remodelling that have a similar function to the haversian system (Holstein *et al.*, 2009). This results in a similar physiological control of bone remodelling (Holstein *et al.*, 2009). Compared to larger animals, mice have much smaller bones, making surgical manipulation more challenging (Muschler *et al.*, 2010). This limitation has been successfully solved with high level technology for small rodents that allows the establishment of highly standardised bone surgical procedures. Even the techniques for the insertion of devices such as intramedullary nails or the placement of fixation plates on the bone have been properly standardised, allowing a closer translation to the clinical situation in human patients (Haffner-Luntzer *et al.*, 2016; Histing *et al.*, 2011).

Mice and humans share more than 90 % genetic homology (Mouse Genome Sequencing Consortium *et al.*, 2002). A recent study has demonstrated that gene expression responses of mice and humans to trauma, burns and endotoxemia are significantly correlated

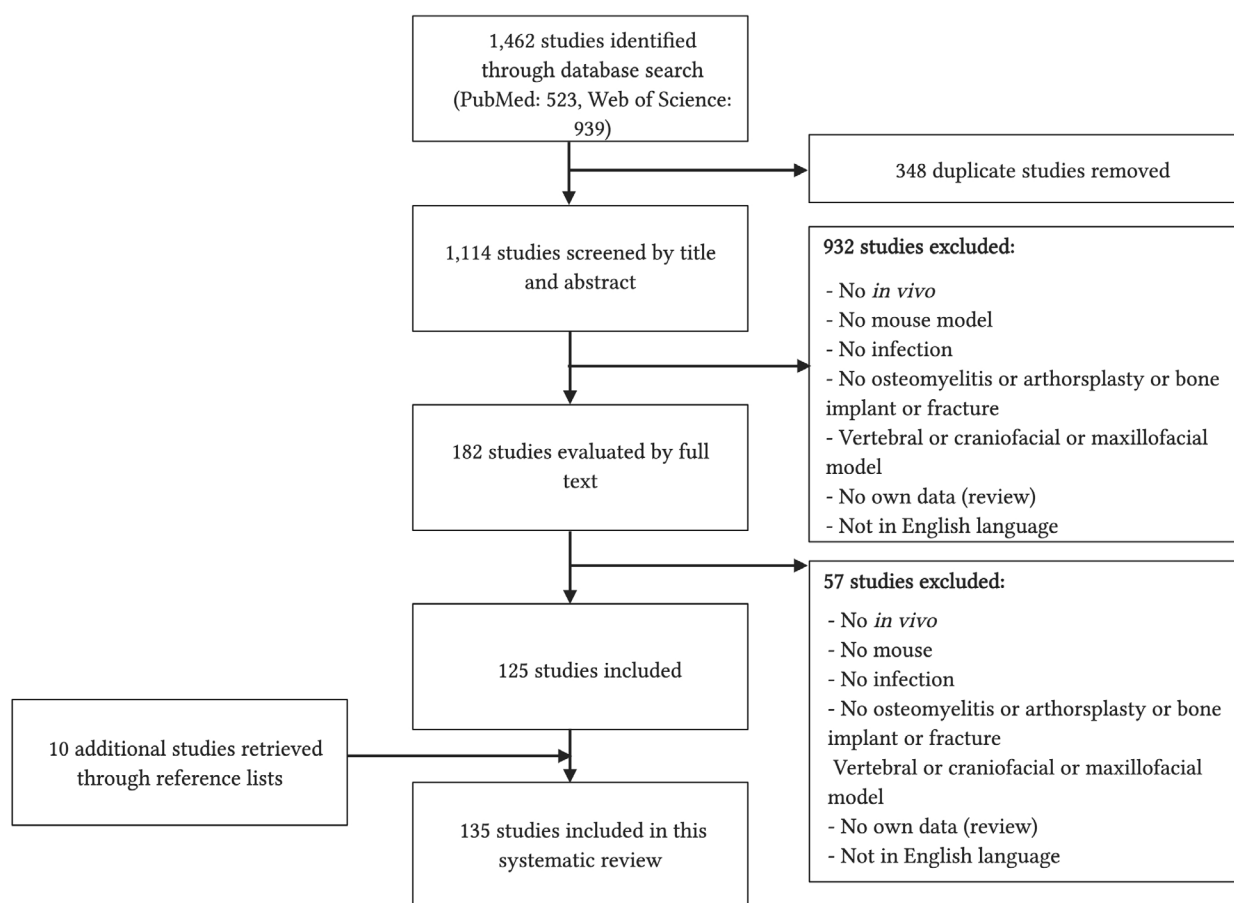

Fig. 2. Schematic flow chart of the steps followed to obtain the collection of studies included in the present systematic review.

(Takao and Miyakawa, 2015). The immune response to osteomyelitis also shows resemblance between mice and humans. For example, pro-inflammatory cytokines involved in the immune response against bacterial infection such as TNF- $\alpha$ , IL-6, IL-1 $\beta$  and IL-17A are upregulated in mouse as well as in human patients in the presence of osteomyelitis (Lüthje *et al.*, 2020; Yoshii *et al.*, 2002b). There are also differences. For example, the chemokine CXCL8, which has a central role in the early defence against infection in humans, has not been identified in mice (Lüthje *et al.*, 2020). On the other hand, anti-inflammatory cytokines such as IL-4 are upregulated in both mice and humans during bone repair after infection (Lüthje *et al.*, 2020). Despite the differences, if the detailed course of the immune responses in mice is known, it is possible to compare the results to the human situation.

Regarding osteomyelitis and pathogenesis, numerous studies have successfully established an infection in the bone, bone fractures and bone with an implant (Bernthal *et al.*, 2010; Horst *et al.*, 2012; Inzana *et al.*, 2015b). The present review discusses the major models described in the literature and their most important characteristics.

### Aim of the review

The aim of the present systematic review is to discuss the different types of mouse osteomyelitis models available, to study the pathophysiology and immune response of the disease and the evaluation of the efficacy of novel preventive and treatment strategies. Based on the model characteristics, the published papers were classified into five subject groups: haematogenous osteomyelitis, post-traumatic osteomyelitis, bone-implant-related infection, PJI and fracture-related infection. In addition, the characteristics of the mice used, such as inbred strain, age or gender, the characteristics of the pathogens used, the inoculation methods, the type of anaesthesia and analgesia used during surgery and the procedures for evaluating the infection are described.

## Materials and Methods

### Search strategy

Two databases, Web of Science (Web ref. 1) and PubMed (Web ref. 2), were used to systematically identify studies exploring osteomyelitis in mouse models. The two databases were strategically searched using the search strategy shown in Fig. 2. The search query used for PubMed was (infection[MESH] OR infection[TIAB]) AND (mice[MESH] OR mice[TIAB] OR mouse[TIAB] OR murine[TIAB]) AND (model[TIAB] OR models[TIAB]) AND (arthroplasty[MESH] OR arthroplasty[TIAB] OR fracture[MESH] OR fracture[TIAB] OR (internal fixator)[MESH] OR (internal fixator)[TIAB] OR (internal fixation)[TIAB] OR prosthesis[MESH]

OR prosthesis[TIAB] OR implant[TIAB] OR osteomyelitis[MESH] OR osteomyelitis[TIAB]). A simpler query was used for Web of Science: (infection) AND (mice OR mouse OR murine) AND (model OR models) AND (arthroplasty OR fracture OR (internal fixator) OR (internal fixation OR prosthesis OR implant OR osteomyelitis)). The final search was conducted on the 15th of March 2021. In addition, other relevant studies found through the reference lists that met the eligibility criteria were included (Fig. 2).

### Inclusion and exclusion criteria

The inclusion criteria were: (1) *in vivo* mouse experimental study, (2) bacterial or fungal osteomyelitis studies, (3) long bones. The exclusion criteria were: (1) no osteomyelitis, (2) no bone infection vertebral osteomyelitis, (3) craniofacial or maxillofacial osteomyelitis, (4) non-infection osteomyelitis, (5) no mouse model, (6) no *in vivo* study, (7) no full-text literature, (8) not written in English language.

### Summary of literature search

Fig. 2 shows the systematic search procedure. A total of 1,462 articles were identified (523 from PubMed and 939 from Web of Science). From those, 348 duplicates were removed. 932 articles were excluded during the initial screening of titles and abstract and 57 during the secondary screening by full reading. 10 additional articles that met the eligibility criteria were retrieved from the reference lists of the papers collected. At the end, 135 studies were included in the present systematic review.

### Model design characteristics

All the studies discovered following the systematic search have in common that they use the mouse as a model to evaluate different aspects of osteomyelitis infection including pathogenesis, prophylaxis and treatment strategies. *S. aureus* was the main bacterial species used in the experimental studies but also other species, such as *A. baumannii* and *E. coli*, were found and are described in the review. A section discussing the main model design characteristics in detail, such as mouse strain, bacterial species, inoculum methods, surgical procedures and evaluation methods, was also included.

The experimental studies were organised into five different categories, each with corresponding tables listing the surgical procedure and bacterial inoculation method used. These categories were haematogenous osteomyelitis, post-traumatic osteomyelitis, bone-implant-related infection, PJI and fracture-related infection (Table 1-6). Each table provides the major details of the published procedure: (1) reference; (2) title; (3) microbiological status of the mice (*e.g.* SPF), gender and strain; (4) age; (5) time points; (6) bacterial strain, inoculum size and volume; (7) inoculation method; (8) evaluation methods. In Table 2, the size and location of the

Xiao <i>et al.</i> , 2017	Detecting chronic post-traumatic osteomyelitis of mouse tibia via an IL-13Rα2 targeted metallofullerene MRI probe	Female BALB/c	8-10 weeks	28 d	<i>S. aureus</i> ATCC 25923, 10 <sup>7</sup> CFU in 150 µL	Pre-inoculation of a virucyl suture for 30 min	Defect in the proximal end of tibia, diameter of 27 G	Luminol-bioluminescence imaging of myeloperoxidase, MRI, histology, IMHC
Loughran <i>et al.</i> , 2016	Impact of sarA and phenol-soluble modulins on the pathogenesis of osteomyelitis in diverse clinical isolates of <i>S. aureus</i>	Female C57BL/6	8-10 weeks	14 d	<i>S. aureus</i> USA300 strain LAC, USA200 UAMS-1, and sarA or alpha class of PSMs mutants, 10 <sup>5</sup> CFU in 2 µL	Inoculation in intramedullary canal	Defect in the lateral midshalf of the femur, diameter of 21 G	µCT, proteomics
Mendoza Bertelli <i>et al.</i> , 2016	<i>S. aureus</i> protein A enhances osteoclastogenesis via TNFR1 and EGFR signalling	BALB/c	10 weeks	14 d	<i>S. aureus</i> FPR3757 and the isogenic SpA-mutant, (1-2) × 10 <sup>6</sup> CFU in 2.5 µL	Inoculation in fibrin	Perforation in the tibia with a diameter of 1 mm	CFU counts (tibia), histology, µCT
Wagner <i>et al.</i> , 2016	Surgical debridement is superior to sole antibiotic therapy in a novel murine posttraumatic osteomyelitis model	Male and female C57BL/6	-	7 and 14 d	<i>S. aureus</i> Rosenbach 1884, 2 × 10 <sup>7</sup> CFU in 0.5 µL	Inoculation in intramedullary canal	Unicortical defect in the proximal medial tibia, diameter of 1 mm	CFU counts, histology, Gram staining, qRT-PCR

Table 2c. Classification of the post-traumatic osteomyelitis mouse models.

Reference	Title	Microbiological status, gender, and strain	Age	Time points	Bacterial strain, inoculum size, volume	Inoculation method	Defect type and hole size (G)	Evaluation
Wilde <i>et al.</i> , 2015	Bacterial hypoxic responses revealed as critical determinants of the host-pathogen outcome by TnSeq analysis of <i>S. aureus</i> invasive infection	Female C57BL/6j	7-8 weeks		<i>S. aureus</i> HG003, 10 <sup>6</sup> CFU in 2 $\mu$ L	Inoculation in femur	Unicortical defect, diameter of 1 mm (21 G)	BLI, transposon seq analysis, qPCR
Cassat <i>et al.</i> , 2013	A secreted bacterial protease tailors the <i>S. aureus</i> virulence repertoire to modulate bone remodelling during osteomyelitis	C57BL/6j	7-8 weeks	14 d	<i>S. aureus</i> USA300 LAC, 10 <sup>6</sup> CFU in 2 $\mu$ L	Inoculation in intramedullary canal	Unicortical defect in the lateral midshaft of the femur, diameter of 1 mm (21 G)	$\mu$ CT, histopathology
Funao <i>et al.</i> , 2012	Establishment of a real-time, quantitative, and reproducible mouse model of <i>Staphylococcus</i> osteomyelitis using bioluminescence imaging	Male BALB/c	12 weeks	3, 7, 21 and 28 d	<i>S. aureus</i> Xen-29 (ATCC 12600), 10 <sup>8</sup> CFU in 1 $\mu$ L	Inoculation in intramedullary canal	Perforation at the distal end of the femur, diameter of 23 G	Flow cytometry, histology, BLI, serology
Sotnik <i>et al.</i> , 2010	Chronic bacterial osteomyelitis suppression of tumour growth requires innate immune responses	Female C3H-HeN, BALB/c, C57BL/6	8-10 weeks	10 d	<i>S. aureus</i> Xen 36 (ATCC 49525), 10 <sup>8</sup> CFU in 1 mL	Pre-inoculation of silk suture	Perpendicular hole in the proximal tibia, diameter of 23 G	Flow cytometry, CFU counts (tibia)
Varoga <i>et al.</i> , 2009	Osteoblasts participate in the innate immunity of the bone by producing human $\beta$ defensin-3	Male BALB/c	8-12 weeks	12 h	<i>S. aureus</i> , 10 <sup>6</sup> CFU/mL in 10 $\mu$ L	Injection in the intraosseous cavity		RT-qPCR and ELISA
Takahashi <i>et al.</i> , 2008	Bone-targeting of quinolones conjugated with an acidic oligopeptide	Female ddY	8-10 weeks		<i>S. aureus</i> JCM 2413, 10 <sup>5</sup> CFU in 1 $\mu$ L	Inoculation in intramedullary canal	Perforation at the proximal third portion of the tibia, diameter of 26 G	CFU counts (tibia)
Varoga <i>et al.</i> , 2008	The role of human $\beta$ -defensin-2 in bone	Male BALB/c	8-12 weeks	12 h	<i>S. aureus</i> , 10 <sup>6</sup> CFU/mL in 10 $\mu$ L	Injection into the intraosseous cavity		RT-qPCR and IMHC
Marriott <i>et al.</i> , 2005	Osteoblasts produce monocyte chemoattractant protein-1 in a murine model of <i>S. aureus</i> osteomyelitis and infected human bone tissue	BALB/c	-	1 and 2 d	<i>S. aureus</i> ATCC 49230, 10 <sup>3</sup> CFU	Agarose beads	Perforation in the bone cortex	IMHC, RT-PCR
Marriott <i>et al.</i> , 2004	Osteoblasts express the inflammatory cytokine interleukin-6 in a murine model of <i>S. aureus</i> osteomyelitis and infected human bone tissue	BALB/c	-	2 and 4 d	<i>S. aureus</i> ATCC 49230, 10 <sup>3</sup> CFU	Agarose beads	Perforation in the bone cortex	IMHC, RT-PCR
Yoshii, 2002a	Inhibitory effect of roxithromycin on the local levels of bone-resorbing cytokines in an experimental model of murine osteomyelitis	Female ICR	5 weeks	1, 3, 5, 7, 14, 21 and 28 d	<i>S. aureus</i> E-31461, 10 <sup>8</sup> CFU/mL	Pre-inoculation of silk suture	Perforation of the tibia, diameter of 23 G	ELISA of IL-1 $\beta$ , IL-6, TNF- $\alpha$
Yoshii <i>et al.</i> , 2002b	Local levels of interleukin-1 $\beta$ , -4, -6, and tumour necrosis factor in an experimental model of murine osteomyelitis due to <i>S. aureus</i>	Female ICR	5 weeks	1, 3, 5, 7, 14, 21 and 28 d	<i>S. aureus</i> E-31461, 10 <sup>8</sup> CFU/mL	Pre-inoculation of silk suture	Perforation of the tibia, diameter of 23 G	CFU counts (tibia), bone histology, ELISA of cytokines

Table 3a. Classification of the bone-implant infection mouse models.

Reference	Title	Microbiological status, gender, strain	Age	Time points	Bacterial strain, inoculum size, volume	Inoculation method, placement of the device	Evaluation
Lin <i>et al.</i> , 2021	mRNA transcriptome analysis of bone in a mouse model of implant-associated <i>Staphylococcus aureus</i> osteomyelitis	Male, C57BL/6	10-12 weeks	14 and 28 d	<i>S. aureus</i> clinical strain, 10 <sup>6</sup> CFU/mL in 2 $\mu$ L	Inoculation at the bone cavity, femoral intramedullary pin	$\mu$ CT, X-ray, CFU counts (bone and implant), histology, immunohistochemistry, immunofluorescence, qRT-PCR
Masters <i>et al.</i> , 2021	Distinct vasculotropic versus osteotropic features of <i>S. agalactiae</i> versus <i>S. aureus</i> implant-associated bone infection in mice	Female BALB/c	6 weeks	14 d	<i>S. aureus</i> USA300 and <i>S. agalactiae</i> COH1, 5 $\times$ 10 <sup>5</sup> CFU/mL	Pre-inoculation of the implants, transcortical tibia pin	CFU counts (bone, implant and tissue), $\mu$ CT, X-ray, histology, TEM, TRAP
Tomizawa <i>et al.</i> , 2021	The limitations of mono- and combination antibiotic therapies on immature biofilms in a murine model of implant-associated osteomyelitis: ceftazolin, gentamicin and vanco with or not rifampicin	Female BALB/c	6-8 weeks	0, 3, 7 and 14 d	<i>S. aureus</i> UAMS-1 2.5 $\times$ 10 <sup>5</sup> CFU	Pre-inoculation of the implants, transcortical tibia pin	CFU counts (implant and tissue), SEM, histology (Brown and Brenn)
Aguilera-Correa <i>et al.</i> , 2020	A new antibiotic-loaded Sol-Gel can prevent bacterial prosthetic joint infection: from <i>in vitro</i> studies to an <i>in vivo</i> model (moxifloxacin)	Male CD1	16 weeks	35 d	<i>S. aureus</i> and <i>E. coli</i> clinical strains	Injection in femoral canal, femoral intramedullary implant	CFU count (bone and implant), histology, $\mu$ CT
Masters <i>et al.</i> , 2020	Identification of penicillin binding protein 4 (PBP4) as a critical factor for <i>S. aureus</i> bone invasion during osteomyelitis in mice	Female BALB/c	6-8 weeks	14 d	<i>S. aureus</i> USA300 or $\Delta$ pbp4, 5 $\times$ 10 <sup>5</sup> CFU/mL	Pre-inoculation of the pins for 20 min, transcortical tibia pin	CFU counts (bone, tissue, implant), $\mu$ CT, X-ray, histology (Brown and Brenn), TRAP, TEM
Tomizawa <i>et al.</i> , 2020	Biofilm producing <i>Staphylococcus epidermidis</i> inhibits osseous integration without osteolysis and histopathology in a murine septic implant model	Female BALB/c	6-8 weeks	7, 14 and 42 d	<i>S. epidermidis</i> RP62a 1.6 $\times$ 10 <sup>5</sup> CFU and <i>S. aureus</i> USA300 LAC 2.1 $\times$ 10 <sup>5</sup> CFU	Pre-inoculation of pins, transcortical tibia pin	CFU counts (tissue and implant), histology, $\mu$ CT, SEM, qPCR biomechanical test
Wang <i>et al.</i> , 2020b	NF- $\kappa$ B/TWIST1 mediates migration and phagocytosis of macrophages in the mice model of implant-associated <i>S. aureus</i> osteomyelitis	Male C57BL/6	8 weeks	3 d	<i>S. aureus</i> , 10 <sup>6</sup> CFU in 2 $\mu$ L	Inoculation in intramedullary cavity, femoral intramedullary implant	RT-qPCR, Western blot, histology, IMHC
Zhang <i>et al.</i> , 2019	Significant suppression of <i>S. aureus</i> colonization on intramedullary Ti6Al4V implants surface-grafted with vancomycin-bearing polymer brushes	Male and female CL57BL/6	8-12 weeks	7, 14 and 21 d	<i>S. aureus</i> Xen29, 10 <sup>4</sup> CFU in 4 $\mu$ L	Inoculation in intramedullary cavity, femoral intramedullary pin	$\mu$ CT, BLL, blood counts, CFU counts (pin), histology
Boles <i>et al.</i> , 2018	Local delivery of amikacin and vancomycin from chitosan sponges prevent polymicrobial implant-associated biofilm	C57BL/6	8-12 weeks	7 d	<i>S. aureus</i> UAMS-1, 10 <sup>4</sup> CFU and <i>E. coli</i> ATCC 25922, 10 <sup>2</sup> CFU	Pre-inoculation of the K-wire, femoral intramedullary K-wire	CFU counts (femur and K-wire)
Jiang <i>et al.</i> , 2019	Aspirin alleviates orthopaedic implant-associated infection	Female C57BL/6J	8 weeks	11 d	<i>S. aureus</i> ATCC 43300, 10 <sup>6</sup> CFU in 1.5 mL	Pre-inoculation of pin, transcortical tibia pin	$\mu$ CT, histology, immunohistochemistry
Wells <i>et al.</i> , 2018	Ciprofloxacin and rifampin dual antibiotic-loaded biopolymer chitosan sponge for bacterial inhibition	C57BL/6	8-12 weeks	7 d	Polymicrobial mixture: <i>S. aureus</i> UAMS-1, 10 <sup>4</sup> CFU and <i>E. coli</i> ATCC 25922, 10 <sup>3</sup> CFU	Pre-inoculation of pin, femoral intramedullary pin	CFU counts (pin and femur)

Table 3b. Classification of the bone-implant infection mouse models.

Reference	Title	Microbiological status, gender, strain	Age	Time points	Bacterial strain, inoculum size, volume	Inoculation method, placement of the device	Evaluation
Harris <i>et al.</i> , 2017	Phosphatidylcholine coatings deliver local antimicrobials and reduce infection in a murine model: a preliminary study	C57BL/6	8-12 weeks	7 d	<i>S. aureus</i> UAMS-1, 10 <sup>4</sup> CFU	Wound inoculation, femoral intramedullary nail	CFU counts (femur and implant)
Ishikawa <i>et al.</i> , 2017	Surface topography of silicon nitride affects antimicrobial and osseointegrative properties of tibial implants in a murine model	Female BALB/c	8 weeks	1, 3, 5, 7, 10 and 14 d	MRSA USA300 LAC, 10 <sup>8</sup> CFU	Pre-inoculation of implants for 20 min, transcortical pin in the tibia	CFU counts (implant), SEM
Jørgensen <i>et al.</i> , 2017	Hyperbaric oxygen therapy is ineffective as an adjuvant to daptomycin with rifampicin treatment in a murine model of <i>S. aureus</i> in implant-associated osteomyelitis	Female C57BL/6J	8-10 weeks	14 d	<i>S. aureus</i> ATCC 12600, 10 <sup>6</sup> CFU/mL	Pre-incubation of implant for 24 h, transcortical pin in the tibia	CFU counts (tibia and implant), serological biomarkers
Funao <i>et al.</i> , 2016	A novel hydroxyapatite film coated with ionic silver via inositol hexaphosphate chelation prevents implant-associated infection	SPF male BALB/c	12 weeks	28 d	<i>S. aureus</i> Xen29 ATCC 12600, 10 <sup>8</sup> CFU in 1 $\mu$ L	Inoculation in intramedullary cavity, intramedullary nail in the femur	BLI, serology, histology
Jørgensen <i>et al.</i> , 2016	Rifampicin-containing combinations are superior to combinations of vancomycin, linezolid and daptomycin against <i>S. aureus</i> biofilm infection <i>in vivo</i> and <i>in vitro</i>	Female C57BL/6J	6-8 weeks	11 and 14 d	<i>S. aureus</i> ATCC 12600, 10 <sup>6</sup> CFU/mL	Pre-incubation of implant for 24 h, transcortical pin in the tibia	CFU counts (implant and tibia)
Shiono <i>et al.</i> , 2016	Delayed <i>Propionibacterium acnes</i> surgical site infections occur only in the presence of an implant	Male BALB/c	12 weeks	1, 3, 7, 14, 28, 56 and 84 d	<i>P. acnes</i> ATCC 51277, 10 <sup>6</sup> CFU in 1 $\mu$ L	Inoculation at the implant tip, femoral intramedullary nail	Histology, optical imaging, SEM, genetic analysis
Choe <i>et al.</i> , 2015	Immunomodulatory peptide IDR-1018 decreases implant infection and preserves osseointegration	Female C57BL/6 J and macrophage Fas-induced apoptosis	6 to 8 weeks	1 and 15 d	<i>S. aureus</i> Xen36, 100 $\mu$ L of 3 $\times$ 10 <sup>10</sup> CFU/mL	Pre-incubation of implant for 20 min, implant in the mid-diaphysis of the femur	TNF- $\alpha$ , MCP-1, IL-6, FLI counts of macrophages, IL-1 $\beta$ , CFU counts (implant and femur), BLI, ultimate force, stiffness, work to maximum load for osseointegration
Nishitani <i>et al.</i> , 2015	Quantifying the natural history of biofilm formation <i>in vivo</i> during the establishment of chronic implant-associated <i>S. aureus</i> osteomyelitis in mice to identify critical pathogen and host factors	Female C57BL/6 and BALB/c	-	1, 3, 7, 14 and 28 d	<i>S. aureus</i> SH100, UAMS-1 and USA300 LAC	Pre-inoculation of the implant, transcortical tibia pin	BLI, SEM, CFU counts (implant, tibia, soft tissue), RNA analysis, percentage of biofilm area
Nishitani <i>et al.</i> , 2015	A diagnostic serum antibody test for patients with <i>S. aureus</i> osteomyelitis	Female BALB/c and C57BL/6	6-8 weeks	14 and 42 d	<i>S. aureus</i> , <i>S. epidermidis</i> , <i>Staphylococcus lysidamensis</i> and <i>E. coli</i> , 5 $\times$ 10 <sup>6</sup> CFU/pin	Pre-inoculation of the pins, transcortical tibia pin	ELISA
Jørgensen <i>et al.</i> , 2014	A modified chronic infection model for testing treatment of <i>S. aureus</i> biofilms on implants	Female C57BL/6J	6-8 weeks	4, 6, 8, 11 and 15 d	<i>S. aureus</i> Xen31 3.2 $\times$ 10 <sup>4</sup> CFU/pin and <i>S. aureus</i> Xen 29 1.7 $\times$ 10 <sup>4</sup> CFU/pin	Pre-incubation of the implant in 50 ml with 10 <sup>6</sup> CFU for 24 h, transcortical tibia pin	Epifluorescence microscopy, confocal microscopy, CFU counts (implant and tibia)

Table 3c. Classification of the bone-implant infection mouse models.

Reference	Title	Microbiological status, gender, strain	Age	Time points	Bacterial strain, inoculum size, volume	Inoculation method, placement of the device	Evaluation
Zhu <i>et al.</i> , 2014	The potential role of increasing the release of mouse b-defensin-14 in the treatment of osteomyelitis in mice: a primary study	Male BALB/c	8-12 weeks	1, 4 and 7 d	<i>S. aureus</i> ATCC 43300, 10 <sup>3</sup> CFU in 10 µL	Inoculation in intramedullary cavity, tibial intramedullary nail	Body weight and temperature, CFU counts (tibia), histology, ELISA, IMHC, interfacial membrane preparation, RT-PCR, Western blot
Varrone <i>et al.</i> , 2014	Passive immunisation with anti-glucosaminidase monoclonal antibodies protects mice from implant-associated osteomyelitis by mediating opsonophagocytosis of <i>S. aureus</i> megaclusters	Female BALB/c	8-10 weeks	0, 3, 5, 7, 10 and 14 d	<i>S. aureus</i> Xen29 UAMS-1	Pre-incubation of pin for 20 min, transcortical pin in the tibia	TEM, SEM, BLI, µCT, histology
Walton <i>et al.</i> , 2014	Comparison of 3 real-time, quantitative murine models of Staphylococcal biofilm infection by using <i>in vivo</i> bioluminescent imaging	Female ICR	6-8 weeks	1, 4, 8 and 35 d	<i>S. aureus</i> Xen36	Pre-incubation of pins, transcortical pin in the tibia	BLI and histology
Gedberg <i>et al.</i> , 2013	Anti-glucosaminidase IgG in sera as a biomarker of host immunity against <i>S. aureus</i> in orthopaedic surgery patients	Female BALB/c	6-8 weeks	42 d	<i>S. aureus</i> clinical strain	Pre-incubation of pin for 20 min, transcortical pin in the tibia	Serum collection for functional titer percentage inhibition
Shandley <i>et al.</i> , 2012	Hyperbaric oxygen therapy in a mouse model of implant-associated osteomyelitis	Male C57BL/6	7-9 weeks	0, 12 and 19 d	<i>S. aureus</i> , 2.7 × 10 <sup>6</sup> CFU, <i>P. aeruginosa</i> , 6 × 10 <sup>4</sup> CFU, <i>K. pneumoniae</i> 1.1 × 10 <sup>6</sup> CFU in 200 µL	Pre-inoculation of pin for 5 min, transcortical pin in the tibia	PCR, ELISA
Prabhakara <i>et al.</i> , 2011	Suppression of the inflammatory immune response prevents the development of chronic biofilm infection due to MRSA	C57BL/6 and BALB/c	6-8 weeks	7, 14, 21, 28 and 49 d	MRSA-M2, 3 × 10 <sup>8</sup> CFU/pin	Pre-incubation of pin for 20 min, transcortical pin in the tibia	CFU counts (tibia), PNA-FISH, cytokines
Prabhakara <i>et al.</i> , 2011	Murine immune response to a chronic <i>S. aureus</i> biofilm infection	C57BL/6	6-8 weeks	4, 7, 14, 21, 28 and 49 d	MRSA-M2 and UAMS-1, 2 × 10 <sup>8</sup> CFU/pin	Pre-incubation of pin for 20 min, transcortical pin in the tibia	ELISA for cytokine level, IgG, flow cytometry, CFU counts(tibia), PNA-FISH of pin
Crane <i>et al.</i> , 2009	Efficacy of colistin impregnated beads to prevent multi-drug resistant <i>A. baumannii</i> implant-associated osteomyelitis	Female C57BL/6	6-8 weeks	19 d	<i>A. baumannii</i> and <i>S. aureus</i> Xen29, 2.5 × 10 <sup>8</sup> CFU	Pre-inoculation of the pin, transcortical pin in the tibia	µCT, histology, serology
Li <i>et al.</i> , 2008	A quantitative mouse model of implant-associated osteomyelitis and the kinetics of microbial growth, osteolysis and humoral immunity	Female C57BL/6	6-8 weeks	0, 4, 7, 11, 14 and 18 d	<i>S. aureus</i> ATCC 49230, 9.5 × 10 <sup>8</sup> CFU; Xen29 (ATCC 12600), 4.2 × 10 <sup>8</sup> CFU	Pre-incubation of pin for 20 min, transcortical pin in the tibia	IVIS, µCT, histology, qRT-PCR, serology
Johansson <i>et al.</i> , 2001	Collagen and fibronectin binding in experimental Staphylococcal osteomyelitis	CBA	6 weeks	28-32 d	<i>S. aureus</i> Phillips and PH100, 10 <sup>9</sup> CFU/mL in 500 µL	Injected in the bone hole, intramedullary tibial steel cerclage	CFU counts (tissue), histology

Table 4. Classification of diabetes and bone-implant infection mouse models.

Reference	Title	Microbiological status, gender, strain	Age	Time points	Bacterial strain, inoculum size, volume	Inoculation method, placement of the device	Evaluation	Diabetes induction
Farnsworth <i>et al.</i> , 2018	Obesity/type 2 diabetes increases inflammation, periosteal reactive bone formation, and osteolysis during <i>S. aureus</i> implant-associated bone infection	Male C57BL/6j		1, 3, 7, 14 and 21 d	<i>S. aureus</i> USA300 LAC, $2 \times 10^8$ CFU/pin	Pre-inoculation of the pins, transcortical tibia pin	Histology, RNaseq, $\mu$ CT, CFU counts (tibia)	High-fat (60 % kcal) or low-fat (10 % kcal) diet for 3 months
Farnsworth <i>et al.</i> , 2017	Adaptive upregulation of ClfA by <i>S. aureus</i> in the obese, T2D host mediates increased virulence	Male C57BL/6j	12 weeks	14 and 21 d	<i>S. aureus</i> JE2 and ClfA mutant strain	Pre-incubation of the pin for 20 min, transcortical tibia pin	CFU counts (tissue and tibia), RT-PCR, histology, immunofluorescence, coagulation assays	High-fat diet (60 % kcal)
Wang <i>et al.</i> , 2017b	Chronic osteomyelitis increases the incidence of T2D in humans and mice	Female C57BL/6	10 weeks		<i>S. aureus</i>	Pre-inoculation of the pin, transcortical tibia pin	X-ray, fasting blood glucose measure	Not mentioned
Farnsworth <i>et al.</i> , 2015	A humoral immune defect distinguishes the response to <i>S. aureus</i> infections in mice with obesity and T2D from that in mice with T1D	Male C57BL/6j	12 weeks	7 and 14 d	<i>S. aureus</i> Xen36, $2 \times 10^8$ CFU	Pre-inoculation of the wire for 20 min, transcortical tibia pin	CFU counts (tibia and tissue), BLI, ELISA	Streptozotoin for T1D and high-fat diet for T2D
Lovati <i>et al.</i> , 2014	Does PGE1 vasodilator prevent orthopaedic implant-related infection in diabetes? preliminary results in a mouse model	Female NOD/ShiLj mice type I diabetic	14 weeks	7, 14 and 28 d	<i>S. aureus</i> ATCC 25923, $1 \times 10^8$ CFU in 3 $\mu$ L	Injection in femoral canal, femoral intramedullary pin	$\mu$ CT, histology, blood analysis, CFU count (femur)	Transgenic mice
Lovati <i>et al.</i> , 2013	Diabetic mouse model of orthopaedic implant-related <i>S. aureus</i> infection	NOD/ShiLj mice and non-diabetic CD1		28 d	<i>S. aureus</i> ATCC 25923, $1 \times 10^8$ CFU in 3 $\mu$ L	Injection in femoral canal, femoral intramedullary pin	$\mu$ CT, histology, blood analysis, CFU count (femur)	Transgenic mice

Table 5a. Classification of the peri-prosthetic joint-implant infection mouse models.

Reference	Title	Microbiological status, gender, strain	Age	Time points	Bacterial strain, inoculum size, volume	Inoculation method, placement of the device	Evaluation
Wang <i>et al.</i> , 2021	CCR2 contributes to host defence against <i>S. aureus</i> orthopaedic implant-associated infections in mice	Male C57BL/6j	8-12 weeks	7, 14 and 21 d	<i>S. aureus</i> USA 300 SAP231 10 <sup>8</sup> CFU in 2 µL	Inoculation on the implant surface, femoral intramedullary implant protruding in the joint (1 mm)	IVIS, CFU counts (bone and implants), flow cytometry
Sosa <i>et al.</i> , 2020	The antimicrobial potential of bacteriophage-derived lysin in a murine debriement, antibiotics, and implant retention model of prosthetic joint infection	Female C57BL/6j	16 weeks	10 d	<i>S. aureus</i> Xen36, 10 <sup>8</sup> CFU	Injection in the knee, press-fit insertion of tibial component	CFU counts (tissue and implants), X-ray
Wang <i>et al.</i> , 2020a	IL-1β and TNFα are essential in controlling an experimental orthopaedic implant-associated infection	Male C57BL/6	8-12 weeks	0, 3, 7 and 14 d	<i>S. aureus</i> Xen36 ATCC 49525, 10 <sup>8</sup> CFU in 2 µL	Inoculation in joint cavity, femoral intramedullary implant protruding in the joint (1 mm)	Flow cytometry
Yamada <i>et al.</i> , 2020	Monocyte metabolic reprogramming promotes pro-inflammatory activity and <i>S. aureus</i> biofilm clearance	Male and female C57BL/6NCR1	8 weeks	7, 14 and 21 d	<i>S. aureus</i> USA300 LAC 13c, 10 <sup>8</sup> CFU in 2 µL	Inoculation on the K-wire, femoral intramedullary implant protruding in the joint (1 mm)	CFU counts (tissue, knee, femur, implant), IVIS, flow cytometry
Sheppard <i>et al.</i> , 2020	Novel <i>in vivo</i> mouse model of shoulder implant infection	Male C57BL/6	12 weeks	1, 3, 5, 7, 10, 14, 18, 21, 28, 35, and 42 d	<i>S. aureus</i> Xen36 (ATCC 49525) 10 <sup>8</sup> and 10 <sup>6</sup> CFU in 2 µL	Inoculation at the implant tip, humerus nail protruding in the joint	IVIS, histology, confocal microscopy, X-ray, CFU counts (tissue and implant)
Zhang <i>et al.</i> , 2020	Surface grafted zwitterionic polymers improve the efficacy of a single antibiotic injection in suppressing <i>S. aureus</i> peri-prosthetic infections	C57BL/6	8-12 weeks	21 d	<i>S. aureus</i> Xen29, 10 <sup>8</sup> CFU/mL in 4 µL	Injection in the femoral canal, femoral intramedullary nail	IVIS, histology, µCT
Hernandez <i>et al.</i> , 2019	Disruption of the gut microbiome increases the risk of peri-prosthetic joint infection in mice	Male C57BL/6	16 weeks	5 d	<i>S. aureus</i> Xen36 ATCC 49525, 10 <sup>8</sup> CFU in 2 µL	Inoculation in joint cavity, press-fit insertion of tibial component	CFU counts (joint and implant), flow cytometry
Peng <i>et al.</i> , 2019	Curcumin µP promising anti-bacterial and anti-inflammatory agent for treating peri-prosthetic joint infections	Male C57BL/6	12 weeks	7 d	<i>S. aureus</i> ATCC 43300, 2 × 10 <sup>8</sup> CFU	Inoculation in intramedullary cavity, femoral intramedullary nail	Inflammatory index score, µCT, histology
Stavrakis <i>et al.</i> , 2019	Controlled release of vancomycin and tige cycline from an orthopaedic implant coating prevents <i>S. aureus</i> infection in an open fracture animal model	Male C57BL/6	Male 12 weeks	3, 14, 28 and 42 d	<i>S. aureus</i> Xen 36 ATCC 49525, 10 <sup>8</sup> CFU in 2 µL	Inoculation in fracture site, femoral intramedullary nail protruding in the joint	X-ray, BLI, CFU counts (tissue and pin)
Carli <i>et al.</i> , 2018	Vancomycin-loaded polymethylmethacrylate spacers fail to eradicate PJI in a clinically representative mouse model	C57BL/6	12 weeks	14 d	<i>S. aureus</i> Xen36 ATCC 49525, 3 × 10 <sup>8</sup> CFU in 2 µL	Inoculation in joint space, press-fit insertion of tibial component	X-ray, SEM
Heim <i>et al.</i> , 2018	Heterogeneity of Ly6G <sup>+</sup> Ly6C <sup>+</sup> myeloid-derived suppressor cell infiltrates during <i>Staphylococcus aureus</i> biofilm infection	Male and female C57BL/6	8 weeks	3, 7, 14 and 28 d	<i>S. aureus</i> USA300 LAC 13c, 10 <sup>8</sup> CFU	Inoculation at the implant tip, femoral intramedullary nail protruding in the joint	Flow cytometry
Thompson <i>et al.</i> , 2018	Mouse model of Gram-negative prosthetic joint infection reveals therapeutic targets	Male C57BL/6	6-8 weeks	1, 3, 7, 14 and 21 d	<i>P. aeruginosa</i> Xen41 (PAO1) and <i>E. coli</i> Xen14 (WS2572)	Inoculated in the knee joint, femoral intramedullary K-wire protruding in the joint (0.5 mm)	µCT, histology, CFU counts (implant and tissue), cytokines
Pickett <i>et al.</i> , 2018	Molecularly specific detection of bacterial lipoteichoic acid for diagnosis of prosthetic joint infection of the bone	Male C57BL/6	6 weeks	3, 7, 14 and 21 d	<i>S. aureus</i> FPR3757 and its isogenic SpA-mutant, 10 <sup>8</sup> CFU in 2 µL	Inoculated in the knee joint, femoral intramedullary K-wire protruding in the joint (0.5 mm)	Flow cytometry, BLI, PET imaging

Table 5b. Classification of the peri-prosthetic joint-implant infection mouse models.

Reference	Title	Microbiological status, gender, strain	Age	Time points	Bacterial strain, inoculum size, volume	Inoculation method, placement of the device	Evaluation
de Mesy Bentley <i>et al.</i> , 2017	Evidence of <i>S. aureus</i> deformation, proliferation, and migration in canaliculi of live cortical bone in murine models of osteomyelitis	Female BALB/c J	8-10 weeks	14 d	<i>S. aureus</i> UAMS-1, $5 \times 10^8$ CFU	Pre-inoculation of pins	TEM, SEM
Carli <i>et al.</i> , 2017	Quantification of peri-implant bacterial load and <i>in vivo</i> biofilm formation in an innovative, clinically representative mouse model of periprosthetic joint infection	C57BL/6	12 weeks	7, 14, 21, 28, 35 and 42 d	<i>S. aureus</i> Xen36, $3 \times 10^5$ CFU, 2 $\mu$ L	Inoculation in joint space, press-fit insertion of tibial component	X-ray, SEM, weight, crystal violet, serum amyloid
Hedge <i>et al.</i> , 2017	Single-dose, preoperative vitamin-D supplementation decreases infection in a mouse model of periprosthetic joint infection	Male C57BL/6j	4 weeks		<i>S. aureus</i> Xen36 ATCC 49525, $10^3$ CFU in 2 $\mu$ L	Pipetted in the joint space, femoral intramedullary nail protruding in the joint (1 mm)	IVIS
Mandell <i>et al.</i> , 2017	Elimination of antibiotic resistant surgical implant biofilms using an engineered cationic amphipathic peptide WLBU2	Female C57BL/6j	12 weeks	3 d	<i>S. aureus</i> SH1000, $10^6$ CFU in 10 $\mu$ L	Inoculation at the joint, femoral intramedullary nail protruding in the joint (1 mm)	CFU counts (femur and implant)
Peng <i>et al.</i> , 2017	<i>S. aureus</i> biofilm elicits the expansion, activation, and polarisation of myeloid-derived suppressor cells <i>in vivo</i> and <i>in vitro</i>	Male C57BL/6j-Tg	12 weeks	8 d	<i>S. aureus</i> ATCC 43300, $2 \times 10^8$ CFU	Inoculation in joint space, femoral intramedullary nail	SEM, flow cytometry, RT-PCR, immunofluorescence staining, confocal microscopy
Thompson <i>et al.</i> , 2017	Oral-only linezolid-rifampin is highly effective compared with other antibiotics for periprosthetic joint infection	Male C57BL/6	6-8 weeks	0, 7, 14, 21, 28, 35 and 42 d	<i>S. aureus</i> SAP23, $10^8$ CFU in 2 $\mu$ L	Inoculation in intramedullary cavity, femoral intramedullary nail protruding in the joint (1 mm)	BLI, CFU counts (tissue and implant), X-ray, $\mu$ CT
Wang <i>et al.</i> , 2017a	Preclinical evaluation of photoacoustic imaging as a novel non-invasive approach to detect an orthopaedic implant infection	Male C57BL/6	10 weeks	1, 2, 3 and 4 d	<i>S. aureus</i> Xen36 ATCC 49525, $10^8$ CFU in 2 $\mu$ L	Inoculation in intramedullary cavity, femoral intramedullary nail protruding in the joint (1 mm)	BLI, FLI
Ashbaugh <i>et al.</i> , 2016	Polymeric nanofiber coating with tunable combinatorial antibiotic delivery prevents biofilm-associated infection <i>in vivo</i>	Male C57BL/6	10 weeks	3, 7 and 14 d	<i>S. aureus</i> Xen36, $10^5$ CFU in 2 $\mu$ L	Pipetted in the top of the implant, femoral intramedullary nail protruding in the joint (1 mm)	BLI, CFU counts (tissue and implant), SEM, X-ray, $\mu$ CT
Kaur <i>et al.</i> , 2016	<i>In vivo</i> assessment of phage and linezolid-based implant coatings for treatment of MRSA mediated orthopaedic device related infections	Female BALB/c	4-6 weeks	1, 3, 5, 7, 10, 15 and 20 d	<i>S. aureus</i> 43300, 10 $\mu$ L of $10^5$ , $10^6$ , $10^7$ , $10^8$ CFU/mL	Injection at the joint space, femoral intramedullary nail protruding in the joint	Histopathology, CFU counts (tissue and implant), cytokines levels, screening of resistant mutants, healing parameters
Stavrakis <i>et al.</i> , 2016	<i>In vivo</i> efficacy of a "smart" antimicrobial implant coating	Male C57BL/6	12 weeks	0, 1, 3, 5, 7, 10, 14 and 21 d	<i>S. aureus</i> Xen36, $10^5$ CFU in 2 $\mu$ L	Inoculation in intramedullary cavity, intramedullary nail in the femur	BLI, CFU counts (tissue and implant), X-ray
Vidlak and Kielian, 2016	Infectious dose dictates the host response during <i>S. aureus</i> orthopaedic-implant biofilm infection	Male IL-12p40 KO and C57BL/6 WT	8 to 12 weeks	7 and 14 d	<i>S. aureus</i> USA300 LAC, $10^3$ or $10^5$ CFU	Inoculation at the implant tip, femoral intramedullary nail protruding in the joint (1 mm)	CFU counts (tissue, joint, femur and implant), flow cytometry, multianalyte microbead arrays
Heim <i>et al.</i> , 2015a	IL-10 production by MDS cells contributes to bacterial persistence during <i>S. aureus</i> orthopaedic biofilm infection	Male IL10GFP, IL-10 KO and C57BL/6	8 weeks	3, 7 and 14 d	<i>S. aureus</i> USA300, $10^3$ CFU	Inoculation at implant tip, femoral intramedullary nail protruding in the joint (1 mm)	ELISA IL-10, flow cytometry, CFU count (tissue, joint and femur), multianalyte microbead, qRT-PCR

Table 5c. Classification of the peri-prosthetic joint-implant infection mouse models.

Reference	Title	Microbiological status, gender, strain	Age	Time points	Bacterial strain, inoculum size, volume	Inoculation method, placement of the device	Evaluation
Heim <i>et al.</i> , 2015b	IL-12 promotes MDS cell recruitment and bacterial persistence during <i>S. aureus</i> orthopaedic implant infection	Male C57BL/6NCR	8 weeks	7, 14, 21 and 28 d	<i>S. aureus</i> USA300 LAC, 10 <sup>8</sup> CFU	Inoculation at the implant tip, femoral intramedullary nail protruding into the joint (1 mm)	Flow cytometry, CFU counts (tissue, joint and femur), qRT-PCR, $\mu$ CT, histology, ELISA
Young <i>et al.</i> , 2015	Regional intrasosseous administration of prophylactic antibiotics is more effective than systemic administration in a mouse model of TKA	Female CD1	7-9 weeks	1, 2, 3 and 4 d	<i>S. aureus</i> Xen36 ATCC 49525, 5 $\times$ 10 <sup>6</sup> CFU in 2 $\mu$ L	Inoculation in intramedullary cavity, femoral intramedullary nail protruding into the joint (1 mm)	CFU counts (tissue), BLI
Scherr <i>et al.</i> , 2015	<i>S. aureus</i> biofilms induce macrophage dysfunction through leukocidin AB and alpha-toxin	Male C57BL/6	8 weeks	3 and 7 d	<i>S. aureus</i> USA LAC 13c, $\Delta$ hla, $\Delta$ lukAB, or $\Delta$ lukAB $\Delta$ hla, 10 <sup>8</sup> CFU	Inoculation at the implant tip, femoral intramedullary nail protruding into the joint (1 mm)	Flow cytometry, CFU counts (tissue, joint, femur)
Bernthal <i>et al.</i> , 2014	Combined <i>in vivo</i> optical and $\mu$ CT imaging to monitor infection, inflammation, and bone anatomy in an orthopaedic implant infection in mice	Male LysEGFP mice	12 weeks	2, 5, 14, 19, 28 and 48 d	<i>S. aureus</i> Xen29 ATCC 12600, 10 <sup>8</sup> CFU in 2 $\mu$ L	Inoculation in intramedullary cavity, femoral intramedullary nail protruding into the joint (1 mm)	$\mu$ CT, BLI
Heim <i>et al.</i> , 2014	Myeloid-derived suppressor cells contribute to <i>S. aureus</i> orthopaedic biofilm infection	Male C57BL/6	8 weeks	7 and 14 d	<i>S. aureus</i> USA300 LAC, 10 <sup>8</sup> CFU	Pre-incubation of the implant, femoral intramedullary nail protruding into the joint (1 mm)	SEM, flow cytometry, $\mu$ CT, histology, multiplex multianalyte bead array, qRT-PCR, T-cell proliferation assay
Niska <i>et al.</i> , 2013	Vancomycin-rifampin combination therapy has enhanced efficacy against an experimental <i>S. aureus</i> PJI	Male C57BL/6J	8 weeks	0, 7, 14, 21, 28, 35, 42 and 49 d	<i>S. aureus</i> Xen36 ATCC 49525, 10 <sup>8</sup> CFU in 2 $\mu$ L	Inoculation in joint space, femoral intramedullary nail protruding into the joint (1 mm)	BLI, X-ray, CFU counts (tissue and implant), histology
Niska <i>et al.</i> , 2012a	Monitoring bacterial burden, inflammation and bone damage longitudinally using optical and $\mu$ CT imaging in an orthopaedic implant infection in mice	Male LysEGFP mice with green myeloid cells	12 weeks	0, 7, 14, 21, 28, 35 and 49 d	<i>S. aureus</i> Xen29 ATCC 12600, 10 <sup>8</sup> CFU in 2 $\mu$ L	Inoculation in joint space, femoral intramedullary nail protruding into the joint (1 mm)	CFU counts (femur and implant), histology, $\mu$ CT imaging, X-ray, BLI

Inzana <i>et al.</i> , 2015a	3D printed bioceramics for dual antibiotic delivery to treat implant-associated bone infection	Female BALB/c	13-15 weeks	0, 1, 4, 7, 10, 13, 16, 19, 22, 25 and 28 d	<i>S. aureus</i> Xen36 ATCC 49525, $8 \times 10^4$ CFU/mL	Incubation of collagen sheet for 2 h, diameter of 0.67 mm, 6-holes fixation plate next to the femur	BLI, X-ray, SEM, CFU counts (femur, tissue, implant)
Inzana <i>et al.</i> , 2015b	A novel murine model of established staphylococcal bone infection in the presence of a fracture fixation plate to study therapies utilizing antibiotic-laden spacers after revision surgery	Female BALB/c	13-15 weeks	0, 1, 5, 7, 10 and 14 d	<i>S. aureus</i> Xen36 ATCC 49525, $8 \times 10^4$ CFU/mL	Incubation of collagen sheet for 2 h, diameter of 0.67 mm, 6-holes fixation plate next to the femur	BLI, X-ray, decalcified histology, SEM, $\mu$ CT, CFU counts (femur, tissue, implant)
Windolf <i>et al.</i> , 2014	Lysostaphin-coated titan-implants preventing localized osteitis by <i>S. aureus</i> in a mouse model	Female BALB/c	10-12 weeks	7 and 14 d	<i>S. aureus</i> ATCC 29213, $1.94 \times 10^8$ CFU in 1 $\mu$ L	Inoculation in the fracture gap, diameter of 0.22 mm, 4-holes fixation plate next to the femur	CFU counts, X-ray, flow cytometry, ELISA (IL-6)
Windolf <i>et al.</i> , 2013	Implant-associated localized osteitis in murine femur fracture by biofilm forming <i>S. aureus</i> : a novel experimental model	Female BALB/c	10-12 weeks	0, 7, 14 and 21 d	<i>S. aureus</i> ATCC 29213, $10^8$ CFU in 1 $\mu$ L	Inoculation in the fracture gap, diameter of 0.22 mm, 4-holes fixation plate next to the femur	Histology, SEM, ELISA (IL-6), CFU counts, flow cytometry, X-ray

unicortical defect are also included. Tables 3, 4 and 5 also list the type of device and placement of the device. In Table 5, the type of diabetes induced is also included. Table 6 also includes the size of the fracture, type of device and placement of the device.

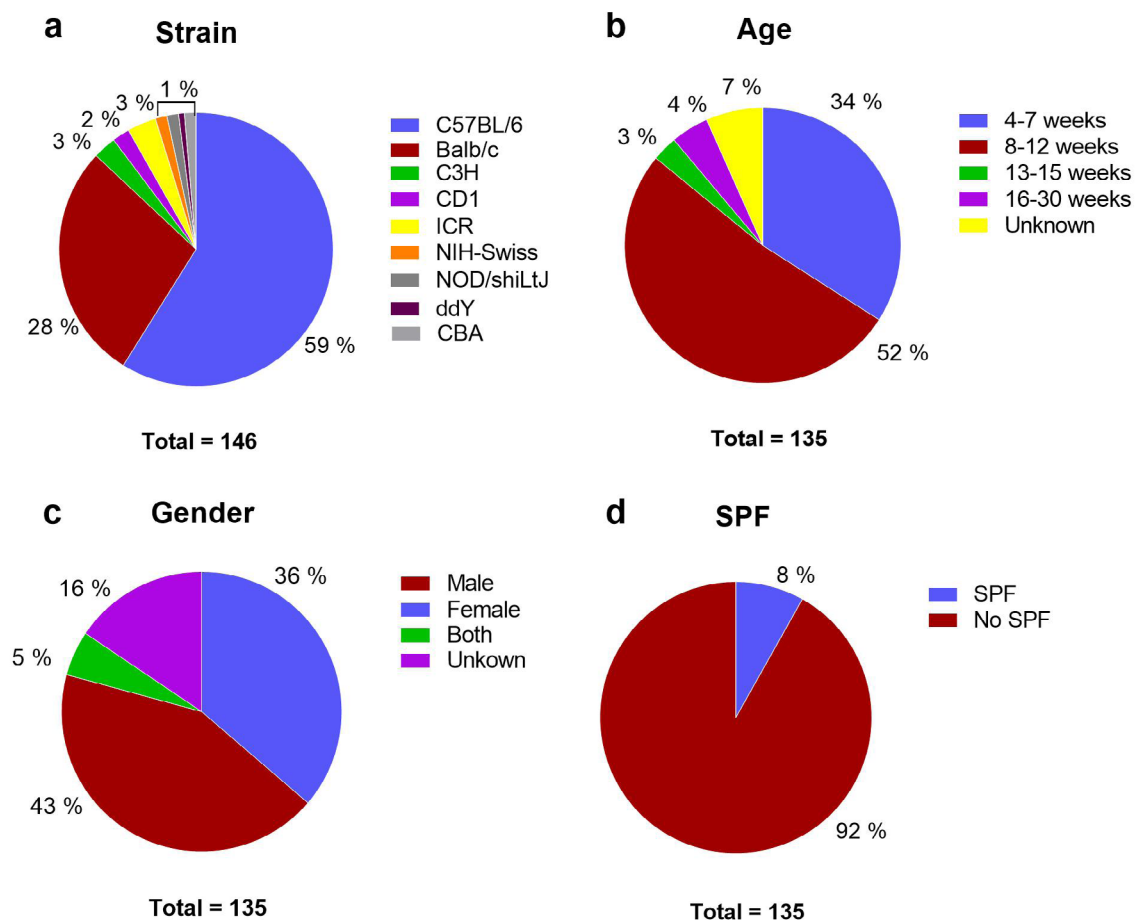

### Analysis of the data

#### Characteristics of the mouse

The studies retrieved in the systematic search have used mice with different characteristics such as inbred strain, age and gender. Differences in mouse strain, age, gender, microbiome composition and the use of conventional or SPF animals could influence the osteomyelitis and fracture healing process. Therefore, it is important to take these characteristics into account to properly choose the animal model.

Inbred mouse strains harbour differences in bone density and bone length. Bone composition differs among inbred mouse strains. For instance, the femur density of C57BL/6J mice (0.45 mg/mm<sup>3</sup>) is significantly lower than that of C3H/HeJ mice (0.69 mg/mm<sup>3</sup>) and of BALB/c mice (0.55 mg/mm<sup>3</sup>). Interestingly, the femur of C3H/HeJ mice is significantly shorter than that of BALB/c and C57BL/6J

mice at all ages measured (Beamer *et al.*, 1996; Kohler *et al.*, 2005). Most researchers selected C57BL/6 (59 %) or BALB/c (28 %) mice for osteomyelitis studies (Fig. 3a). Regarding infection development, in a fracture-related infection study using *S. epidermidis*, BALB/c mice showed larger bacterial counts and formation of larger abscesses compared to C57BL/6 mice (Sabaté Brescó *et al.*, 2017). In cases of infection with *S. aureus*, opposite results were observed regarding the ability of C57BL/6 and BALB/c mice to clear the infection in a bone-implant-related infection study (Nishitani *et al.*, 2015b; Prabhakara *et al.*, 2011b). The authors observed that 58 %, 50 % and 75 % of the BALB/c mice cleared the infection at 21, 28 and 49 d post-infection, respectively; while 100 % of the C57BL/6 mice were unable to clear the infection even 49 d post-infection (Prabhakara *et al.*, 2011b). Moreover, a study comparing *S. aureus* infection, using a bioluminescent *S. aureus* strain, in C57BL/6 and BALB/c mice only showed a brief peak of high intensity bioluminescence at 3 d in the BALB/c strain, characterising active infection, while the C57BL/6 showed high bioluminescence intensity that extended from day 3 through day 7 (Nishitani *et al.*, 2015b). The immune system of C57BL/6 and BALB/c mice differs (Sellers *et al.*, 2012), with C57BL/6 mice being more differentiated towards a Th1-like phenotype

**Fig. 3.** Classification of the osteomyelitis mouse models by (a) mouse strain, (b) age, (c) gender and (d) SPF. 135 studies were included in the graphs. In panel a, some studies included more than one inbred strain. Therefore, there is a total number of 146 studies.

and BALB/c mice towards a Th2-like phenotype in the presence of an *S. aureus* infection (Prabhakara *et al.*, 2011b). This needs to be further investigated to understand the response in each mouse strain and allow the researcher to choose the proper mouse strain for a study.

The animal ages determines to the quality of their bones and the time required for complete healing of a fracture (Ferguson *et al.*, 2003; Haffner-Luntzer *et al.*, 2016). A faster healing process will reduce the risk and period of the infection. Mice are sexually mature at 6-8 weeks of age (Jilka, 2013). Therefore, mice of this age (34 %) or slightly older (9-12 weeks, 52 %) are often selected for osteomyelitis studies because their bones are no longer growing (Fig. 3b). Some authors emphasise the importance of using older mice, 16-30 weeks old, when the animals reach skeletal maturity (Rochford *et al.*, 2016; Sabaté Brescó *et al.*, 2017); however, those are less often used (7 %). The skeletal maturity is characterised by the larger size and greater strength of the bones but also by the degree of mineralisation (Ferguson *et al.*, 2003). The peak of mineralisation is not achieved until an age of 20 weeks in C57BL/6 mice (Brodt *et al.*, 1999; Ferguson *et al.*, 2003).

The animal gender may also influence the healing of the bone and development of infection. For example, hormonal cycles in the females can have a significant influence on bone repair. On the other hand, males are more territorial and may require separate cages to avoid fighting, making them more labour-intensive and expensive to keep (Mills and Simpson, 2012). Of the osteomyelitis *in vivo* studies collected in the present review, 36 % used male mice, 43 % used female mice, 5 % used both genders and 16 % did not mention the gender (Fig. 3c).

The gut microbiome is composed of a wide range of species of microorganisms, including bacteria, yeast and viruses, and provides essential health benefits to its host, particularly by regulating the immune homeostasis (Vlasova *et al.*, 2019). A recent study has revealed that changes in the gut microbiome can influence the development of bone infections in mice (Hernandez *et al.*, 2019). Mice with a disrupted microbiome are more likely to develop a bone infection than mice with a non-modified microbiome; moreover, mice with a disrupted microbiome also show a reduced immune response to the infection (Hernandez *et al.*, 2019). However, more research is necessary to better understand how the gut microbiome influences the response to the infection and help researchers to decide on the optimal features of the mouse strain to select for an *in vivo* study (Hernandez *et al.*, 2019). Moreover, to reduce the presence of unwanted infections affecting the experiments, some researchers prefer to use SPF animals. The use of SPF animals has the additional benefits of being cost-saving as it minimises the number of animals used for a study (Letson *et al.*, 2019). However, SPF animals may have undesired

changes in their immune system that may be linked to modifications in their gut microbiome (Letson *et al.*, 2019). 8 % of the studies analysed in the present review chose SPF mice for their *in vivo* osteomyelitis studies (Funao *et al.*, 2016; Horst *et al.*, 2012; Isogai *et al.*, 2020; Rochford *et al.*, 2016; Sabaté Brescó *et al.*, 2017; Szafranska *et al.*, 2014) but in 92 % of studies conventional mice were used (Fig. 3d).

### Bacterial species related to osteomyelitis

*S. aureus* has been the main bacterial species chosen (90 %) for *in vivo* experiments because it is the most common pathogen causing osteomyelitis (Kavanagh *et al.*, 2018; Fig. 4a). Its ability to cause osteomyelitis is related to the presence of features, known as virulence factors, that allow the bacteria to attach to bones and foreign bodies and form biofilms, to evade the immune system and to cause harmful toxic effects. These virulence factors can be classified by their function as adherence factors, immunomodulatory factors, enzymes and toxins. In the present review, relevant virulence factors were identified and further described below.

Adherence virulence factors such as bacterial adhesins or coagulase can be crucial for bacterial attachment and establishment of an infection. Bacterial adhesins are proteins present on the bacterial surface that can interact with and bind to eukaryotic extracellular (matrix) proteins. Among these adhesins, Cna, FnbA and FnbB are relevant for tissue colonisation and development of bone infections. FnbA and FnbB are present in 98 % and 99 % of clinical isolates from osteomyelitis, respectively (Arciola *et al.*, 2005a). An *in vivo* mouse study has shown the essential role of Cna in the bone colonisation by comparing the infectivity of the *S. aureus* UAMS-1 (ATCC 49230) strain expressing Cna and FnbA and its isogenic Cna mutant known as *S. aureus* UAMS-237 (Elasri *et al.*, 2002). The strain UAMS-1 is an isolate derived from the clinical strain USA200 and is one of the most widely used *S. aureus* strains in osteomyelitis research (Li *et al.*, 2008). Only the Cna positive bacterial strain was able to colonise the murine tibia (Elasri *et al.*, 2002). Thus, to be able to establish an infection in the bone it is necessary to use a Cna positive strain.

Immune evasion is also an important virulence factor for bacteria to establish and maintain the infection in the bone. *S. aureus* has developed strategies to persist and evade clearance by the immune system and establish a chronic bone infection (Tuchscherer *et al.*, 2017). For example, SigB is an important transcription factor contributing to the avoidance of bacterial clearance by the immune response (Tuchscherer *et al.*, 2017). *S. aureus* lacking SigB induces large numbers of small abscesses, which contributes to the elimination of the bacteria in murine osteomyelitis (Tuchscherer *et al.*, 2017). The study also showed that a deletion of *sigB* results in a reduced production of SarA (Tuchscherer *et al.*,

2017). SarA plays a key role in the establishment of the osteomyelitis in a haematogenous murine model (Blevins *et al.*, 2003). A deletion of *sarA* in *S. aureus* UAMS-1 and *S. aureus* RN6390 results in a significantly reduced number of CFU compared to the wild-type strains (Blevins *et al.*, 2003).

The extent of bone destruction caused by the infection is also related to virulence factors such as toxins, *e.g.* PSMs. PSMs are amphipathic peptides with functions as cytotoxins and pro-inflammatory inducers (Cassat *et al.*, 2013). The role of PSMs was studied in an osteomyelitis mouse model indicating that PSMs cause osteoblast cell death and contribute to the destruction of the bone (Cassat *et al.*, 2013; Loughran *et al.*, 2016).

Although antimicrobial resistance is not a virulence factor, in certain situations it is a key factor in the development of an infection and it may be considered to be a virulence-like factor. Antimicrobial resistance plays a key role in persistent osteomyelitis due to the fast development of resistance to multiple antibiotics and the difficulty in treating these infections, causing a persistent osteomyelitis. MRSA is responsible for 40-60 % of all *S. aureus* infections. Therefore, several authors chose MRSA strains for the osteomyelitis mouse model (Jørgensen *et al.*, 2014; Loughran *et al.*, 2016). In addition, it is important to consider the antimicrobial resistance profile of the bacterial strain when testing antimicrobial strategies. Nevertheless, the resistant strain needs to be virulent

enough, with the presence of virulence factors such as adhesins, to establish an infection in the first place.

90 % of the mouse osteomyelitis studies included in the present review were focused on *S. aureus* infections (Fig. 4a). However, other bacterial pathogens can cause osteomyelitis and can also be used to establish an infection and further understand the pathophysiology of the disease. For example, Sabaté Brescó *et al.* (2017) compared the development of fracture-related infection caused by *S. aureus* JAR 06.01.31 and *S. epidermidis* 103.1. Compared to *S. aureus*, *S. epidermidis* infection was less intense, leading to fewer bacteria, causing less bone damage and affecting less the animals' weight. Tomizawa *et al.* (2020) compared the pathogenic potential of an *S. epidermidis* strain RP62a versus *S. aureus* strain USA300, both methicillin-resistant strains, in a bone-implant-related infection mouse model. As expected, *S. aureus* caused a more aggressive and damaging osteomyelitis than *S. epidermidis*. Nevertheless, *S. epidermidis* formed a large biofilm on the implant and caused less inflammation than *S. aureus*.

Shandley *et al.* (2012) aimed to establish a bone-implant-related infection in mice with *S. aureus*, *P. aeruginosa* and *K. pneumoniae* to evaluate the antimicrobial activity of hyperbaric oxygen therapy. Their results showed that *P. aeruginosa* and *S. aureus* are equally capable of establishing the infection in the bone. However, *K. pneumoniae* was not able to infect the bone well and was cleared before infection

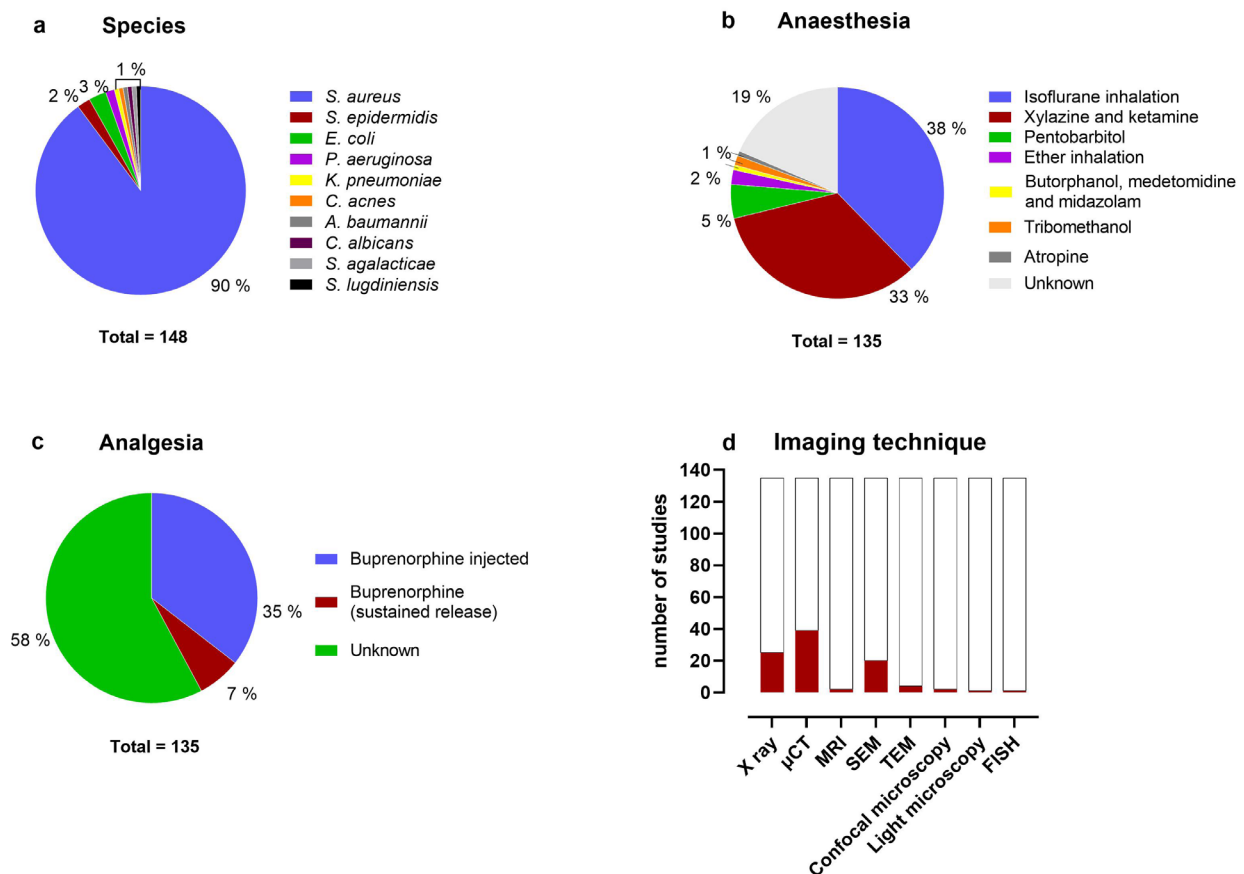

Fig. 4. Classification of the osteomyelitis mouse models by (a) bacterial or fungal pathogen used to infect the animals, (b) image technique used to assess the infection, (c) anaesthesia used to perform the surgery and (d) analgesia used after the surgery. 135 studies were included in the graphs.

was established. Boles *et al.* (2018) established a polymicrobial infection with *S. aureus* UAMS-1 and *E. coli* ATCC 25922 in a mouse implant infection model. *E. coli* was not found either in bones or on implants after 7 d.

Crane *et al.* (2009) studied the efficacy of colistin beads in an implant-related osteomyelitis mouse model infected with *S. aureus* or *A. baumannii* clinical isolates. In contrast to the osteolytic response in the presence of *S. aureus*, *A. baumannii* caused an osteoblastic bone formation response around the infected devices. *S. aureus* was also associated with the presence of biofilm in necrotic bone sections, whereas no biofilm was found in the necrotic tissue in the animals infected with *A. baumannii* (Crane *et al.*, 2009). Shiono *et al.* (2016) studied the development of osteomyelitis by *C. acnes* with and without a titanium bone implant. *C. acnes* survived attached to the implant for 6 months, causing a delayed infection, while it only survived 28 d in the control group without an implant (Shiono *et al.*, 2016). Masters *et al.* (2021) studied the pathogenesis of *S. agalacticae* versus *S. aureus* in a bone implant infection model. Their results showed that *S. agalacticae* colonies were only retrieved from the soft tissue and bone but not from the implant after 14 d of infection. *S. agalacticae* caused less osteolysis and no loss of weight compared to *S. aureus*. Moreover, their TEM images revealed the vasculotropic pathogenesis of *S. agalacticae* compared to the osteotropic behaviour of *S. aureus* (Masters *et al.*, 2021).

To summarise, it is advisable to consider all of these bacterial features (*e.g.* bacterial species, virulence factors and antimicrobial resistance profile) when choosing the appropriate bacterial strain for the intended *in vivo* osteomyelitis mouse studies. In addition, the use is recommended of a strain with a well-documented origin, phenotypic and genotypic profile (and to ensure availability of the strain in view of repeatability and reproducibility of the experiments), proved pathogenicity of the strain and strain characteristics (*e.g.* biofilm formation, panel of adhesins, bacterial toxins and antimicrobial resistance) (Moriarty *et al.*, 2019).

### Inoculation method and dose

Depending on the research question, the bacterial inoculum can be administered in different ways. To mimic a contamination during trauma or surgery, the inoculum can be administered during implantation or defect/fracture formation by pipetting it onto the wound site or applying it using an injector along or in the vicinity of the implant, bone defect or fracture (Thompson *et al.*, 2017). It is advisable to use a low volume for the inoculum to prevent dispersion of the inoculum to other tissues. Therefore, 56 of the studies analysed in the present review used a small inoculum between 1 and 5  $\mu\text{L}$  (Tables 2-6).

To mimic a device contamination, the devices are pre-inoculated with the bacterial strain overnight or briefly before surgery (de Mesy Bentley *et al.*, 2017;

Ishikawa *et al.*, 2017; Li *et al.*, 2008; 2017; Pribaz *et al.*, 2012; Thompson *et al.*, 2017). This method can be applied to evaluate the antimicrobial efficacy of contact-killing or antifouling surfaces (Ishikawa *et al.*, 2017). Moreover, the pre-inoculation of the device can be used to create established biofilms to study an advanced stage of the infection and to evaluate more challenging antimicrobial treatment regimes. Nevertheless, it is advisable to not use a pre-inoculation method to evaluate the antimicrobial activity of a drug delivery system because the device may release the drug before the surgical implantation and the bacteria may be killed prior to implantation.

The injury can also be contaminated from the insertion of a surgical material into the wound such as a pre-inoculated silk suture (Yoshii, 2002a; Yoshii *et al.*, 2002b), pre-inoculated agarose beads (Marriott *et al.*, 2004; Marriott *et al.*, 2005) or a pre-inoculated collagen sheet (Inzana *et al.*, 2015b).

To mimic a late infection or haematogenous infection, the inoculum is injected into the bloodstream at a later point, for example, *via* the lateral tail vein (Blevins *et al.*, 2003; Chadha *et al.*, 1999; Elasri *et al.*, 2002; Horst *et al.*, 2012; Szafranska *et al.*, 2014; Tuchscher *et al.*, 2017; Yoon *et al.*, 1999) or the retro-orbital sinus (Potter *et al.*, 2020; Wang *et al.*, 2017c). In these models, a larger inoculum volume, between 100 and 1,000  $\mu\text{L}$ , is used to allow the inoculum to distribute throughout the bloodstream thus mimicking the haematogenous model.

In general, to create an osteomyelitis mouse model, it is advisable to perform dose-determining studies to establish the dose required to initiate a bone infection. The data collected in the present review show that a certain range of both injection volumes and numbers of CFU are used to establish a bone infection (Tables 1-6).

### Anaesthesia and analgesia in osteomyelitis models

The discomfort of the animals must be maximally reduced for ethical reasons but also because of the potentially adverse influence on experimental outcomes (Moriarty *et al.*, 2019). Mouse anaesthesia demands a thorough knowledge of the mouse physiology and of the pharmacology of the anaesthetics and analgesics in the animals. Depending on the objectives of the experimental procedure, anaesthetics and analgesics can be administered through injection or inhalation (Adams and Pacharinsak, 2015; Gargiulo *et al.*, 2012). In this section, the anaesthetics and analgesics that have been used for these osteomyelitis mouse models will be discussed.

In 40 % of the 135 studies considered in the present review, mice were anaesthetised by inhalation and in 60 % by injection. Inhaled anaesthetics, such as isoflurane, require the use of nose-cone ventilation during surgery, limiting the possibility of adjusting the mouse position, which usually is necessary to create a bone defect or fracture. Inhalation anaesthesia provides greater safety for prolonged

procedures than injectable anaesthetics to maintain the animals in an anaesthesia of sufficient depth. Moreover, inhaled anaesthetics provide more control on the dose administered to the animal and are associated with a quicker recovery compared to injectable anaesthetics (Buitrago *et al.*, 2008). In the osteomyelitis mouse studies, 38 % of the studies used isoflurane and only 2 studies (2 %) used ether as inhaled anaesthetic (Yoshii *et al.*, 2002a; 2002b, Fig. 4b). Injectable anaesthetics permit an easier manipulation of the animals during the surgical procedure, where the animals can undergo various positional changes during the process of creation of bone defect or fracture, which may be required for the placement of a fixation device (nail or plate). However, for longer surgical procedures, the use of inhaled anaesthetics is recommended to avoid the animals awakening during surgery. The most common injectable anaesthetics used within the osteomyelitis mouse models were the combination of xylazine and ketamine (33 %), which are inexpensive, easy to administer and pose no health risks to the researchers (Fig. 4b). Moreover, this combination provides good immobilisation with, additionally, a certain degree of analgesia. Unfortunately, the injectable anaesthetics may present a higher risk of overdose and cardiovascular and respiratory depression that may lead to an increased animal mortality (Buitrago *et al.*, 2008).

Regarding the analgesics, they are administered before and after the surgical procedure. 35 % of the studies injected between 0.01 and 0.05 mg/kg of buprenorphine (Pribaz *et al.*, 2012; Shandley *et al.*, 2012). In several studies (7 %), a polymeric matrix with buprenorphine was inserted into the wound to provide a sustained release of the drug for 72 h to minimise any additional distress (Niska *et al.*, 2012a; Stavrakis *et al.*, 2016; Wang *et al.*, 2017a; Fig. 4c). However, in most of the studies (58 %), the analgesic procedure used was not specified.

### Osteomyelitis evaluation assays

The development of an infection in the bone and surrounding tissue and its effects on the tissue can be evaluated using different techniques. Most authors performed similar assays to analyse the development of infection in the osteomyelitis mouse models. These techniques were classified into three categories: (i) quantification of the infection development, (ii) image analysis and (iii) histomorphological analysis.

#### Quantification of the infection development

To evaluate how the infection develops over time, it is advisable to perform a quantification of the number of bacteria present at different time points. 80 of the studies (59 %) evaluated the infection development by euthanising the animals at different time points, collecting bones, implants, surrounding tissues and/or organs and performing microbial culture to quantify the numbers of CFU (Kaur *et al.*, 2016;

Nishitani *et al.*, 2015b; Niska *et al.*, 2012a; Tomizawa *et al.*, 2020a; Young *et al.*, 2015).

The quantification of infection can also be performed by qRT-PCR (Crane *et al.*, 2009; Li *et al.*, 2008; Wagner *et al.*, 2016). This method allows distinguishing and quantifying between different bacterial species and is even considered to discriminate metabolically active and dormant bacteria.

Other authors used a non-invasive *in vivo* quantification method with BLI of bacteria to follow the infection development in single animals over time. The use of bioluminescent bacteria means that fewer animals are needed because the same animal can, in principle, be used to assess the degree of the infection at every time point over the course of the experiment (Bernthal *et al.*, 2010; Li *et al.*, 2008; Pribaz *et al.*, 2012). One limitation of the bioluminescence technique is the loss of signal during the experiment due to the possible loss of the plasmid that carries the bioluminescence *lux* in the bacterial strain. Therefore, the use of a bacterial strain with *lux* inserted in the chromosome is advisable to not lose the bioluminescence signal over time. However, the bioluminescent signal can also disappear due to metabolic inactivity of the bacteria, which may be the consequence of biofilm formation. This will also happen with strains carrying *lux* in their chromosome. Therefore, this limitation should always be kept in mind when using bioluminescence monitoring of infections. The number of CFU, as derived from the bioluminescence readings at the last time point, should always be confirmed by comparison with the actual numbers of cultured CFU obtained from the specimens following animal sacrifice.

The following examples illustrate the possible difficulty in interpreting bioluminescence signals. The *S. aureus* ALC 2906 strain, which carries the bioluminescence construct on a chloramphenicol-resistance-gene-containing plasmid, had a detectable bioluminescence signal at 10 d in a PJI mouse model. Then, the plasmid was lost due to the lack of pressure for antibiotic selection by chloramphenicol (Pribaz *et al.*, 2012). On the other hand, *S. aureus* Xen 36 strain (ATCC 45925 as genetic background) had higher bioluminescence signals than Xen 40 strain (UAMS-1 as genetic background) but there were no differences in biofilm formation between the strains nor in numbers of CFUs cultured from the implant at 42 d post-infection (Pribaz *et al.*, 2012). It is also important to consider that the bioluminescence signal intensity has been reported to be up to 10-fold higher in BALB/c mice than in C57BL/6 mice due to the differences in light absorption in the respective white *versus* black pigmented skin and hairs of these mouse strains (Nishitani *et al.*, 2015b).

A novel imaging modality based on ultrasound, known as photoacoustic imaging, was also used to follow the development of an infection (Wang *et al.*, 2017a). In this technique, laser pulses are

directed into the body at a specific wavelength to excite a photoacoustic tracer molecule present in the target tissue. The authors conjugated the tracer molecule indocyanine green to beta-cyclodextrin, a polysaccharide taken up by bacteria but not by host cells. Photoacoustic imaging provided significantly deeper tissue penetration (30-50 mm) than BLI (10-20 mm) (Wang *et al.*, 2017a).

#### Image analysis

Advanced imaging techniques such as conventional radiography (Carli *et al.*, 2018; Rochford *et al.*, 2016),  $\mu$ CT (Niska *et al.*, 2012a) and MRI (Horst *et al.*, 2012) provide three-dimensional images of the bone structure. In most cases, these techniques were used to evaluate the structural effects of the infection in the bone (*e.g.* bone destruction and inflammation) and on the fracture healing process (Fig. 4d). These methods of visualisation were also used to check proper placement of the orthopaedic device upon implantation (Trombetta *et al.*, 2019a). In addition,  $\mu$ CT scans can reveal detailed information about tissue mineral density, total callus volume and bone volume fraction of the callus, allowing for evaluation of the bone regeneration process after trauma or fracture. Although  $\mu$ CT scans can also be applied *in vivo*, *ex vivo*  $\mu$ CT scans provide a significantly higher resolution because *ex vivo* a higher dose of X-ray irradiation can be used (Bernthal *et al.*, 2014; Laperre *et al.*, 2011; Niska *et al.*, 2012a).

MRI is one of the imaging modalities of choice for osteomyelitis diagnosis in humans because it provides excellent anatomical detail and it is non-invasive and highly sensitive for detecting an early infection. Horst *et al.* (2012) used MRI to monitor the development of the osteomyelitis during the acute phase of the infection in mice and its progression into a chronic infection. MRI allowed studying the presence of inflammation as well as the bone thickness and deformation in the mouse tibia (Horst *et al.*, 2012).

Other imaging techniques used on *ex vivo* samples are SEM (16 %), TEM (3 %) and confocal microscopy (1 %). Several authors have used SEM to evaluate the bacterial biofilm formation on the surface of the bone tissue or/and inserted devices (Carli *et al.*, 2018; Sabaté Brescó *et al.*, 2017; Trombetta *et al.*, 2019a; Windolf *et al.*, 2013). TEM can also be used to obtain bone tissue images with a higher magnification and resolution than SEM. For example, de Mesy Bentley *et al.* (2017) used TEM to assess and analyse the invasion of *S. aureus* into the bone and the remodelling of the bone tissue. Moreover, the use of TEM has shown the formation of *S. aureus* colonies within the non-mineralised collagen matrix and located intracellularly within neutrophils (Masters *et al.*, 2021).

#### Histomorphological analysis

Histological staining methods were developed to assess and analyse the progression of infection in

the bone and the remodelling process of the bone fracture and surrounding tissues (Rochford *et al.*, 2016; Sabaté Brescó *et al.*, 2017; Windolf *et al.*, 2013; Yokogawa *et al.*, 2018). This technique can identify bacteria and distinguish between different cell types such as osteoblasts, osteoclasts and neutrophils as well as between structural features of the infected tissue. These structural changes in the tissues are well-established for humans and are used to diagnose osteomyelitis in clinical practice.

The histological examination of the osteomyelitis mouse model developed by Horst *et al.* (2012) was performed during the acute and chronic phase of the osteomyelitis and compared to histological tissue samples from a patient with acute osteomyelitis and a patient with chronic osteomyelitis. The histological sections revealed a massive influx of granulocytes, with an intense bacterial colonisation and necrosis, during acute infection at 7 d that was similar to that seen in the human acute osteomyelitis sections. At 21 d, in the stage of chronic infection, the mouse sections revealed osteoclastic resorption with new bone formation similar to the human chronic osteomyelitis sections (Horst *et al.*, 2012). Another osteomyelitis mouse study, that used histological staining, included a scoring system of the sections according to the level of cells infiltration, with scores of 0 for no osteomyelitis, 1 for minimal or rare (<10 % tissue involvement), 2 for mild (10-20 %) and 3 for frequent (20-50 %) osteomyelitis (Lee *et al.*, 2002). Haematoxylin and eosin staining was performed to stain tissue and cells, Gram staining for bacteria. Similarly, Büren *et al.* (2019) developed a standardised histological score system for a bone-fracture-related infection model to evaluate the severity of the infection in the mouse. Their score system evaluated 4 independent histological parameters: (i) presence of callus, (ii) consolidation of the osteotomy, (iii) structural changes of the medullary cavity, (iv) number of bacteria. The presence of callus and the consolidation of the osteotomy were evaluated using haematoxylin-eosin staining and the quantification of bacteria was performed following Giemsa staining (Büren *et al.*, 2019). These examples illustrate the usefulness of histological scoring systems for a semi-quantitative evaluation of histology in mouse osteomyelitis models.

#### Literature review of osteomyelitis mouse models

135 osteomyelitis infection mouse studies were collected, analysed and classified into the following 5 categories: (i) haematogenous osteomyelitis (11 %), (ii) post-traumatic osteomyelitis (22 %), (iii) bone-implant-related infection (28 %), (iv) PJI (26 %), (v) fracture-related infection (13 %) (Fig. 5a). The haematogenous osteomyelitis models are characterised by the bacterial or fungal colonisation of the bone through the bloodstream. The post-traumatic osteomyelitis models represent the local infection of the bone following unicortical defect or trauma. The bone-implant-related infection models

mimic the development of an infection in the presence of a foreign body in the bone. The PJI models mimic the development of an infection in the presence of a device in the bone and synovial fluid. The fracture-related infection models represent the development of an infection in a bone fracture. The authors studied the course of the infection either in the femur (58 %), tibia (37 %), femur and tibia (2 %), humerus (1 %) or radius (1 %) (Fig. 5b). The mouse femur was selected more often than the tibia, for several reasons. The femur is tubular, larger and thicker than the tibia, thus facilitating the insertion of large devices. Moreover, the curvature of the tibia may complicate the insertion of longer devices. Lastly, the proximity of the fibula to the tibia can influence the development of the infection and the healing of the bone.

#### Haematogenous osteomyelitis mouse models

Haematogenous osteomyelitis takes place following a symptomatic or asymptomatic bloodstream infection that allows the pathogen to reach the bone. Worldwide incidence of haematogenous osteomyelitis is 1:1,000-20,000 people, with half of the cases occurring in children younger than 5 years (Popescu *et al.*, 2020).

Generally, microorganisms will arrive at the metaphyses of long bones (*i.e.* femur or tibia), since these are highly vascularised. The lower fluid flow at the bone metaphysis allows the microorganism to establish an infection and cause local inflammation. In the haematogenous mouse infection models' studies reviewed, the inoculum volume used to establish the infection was between 100 and 150  $\mu\text{L}$  and a dose between  $10^6$  and  $10^8$  CFU, with the inoculum administered by injection *via* the retro-orbital venous sinus, intravenously or *via* the lateral tail vein (Table 1; Fig. 6a). 33 % of the bone haematogenous infection studies evaluated the presence of infection in the femur, 40 % in the tibia and 20 % in both tibia and femur (Fig. 7a). In most of the haematogenous studies, no trauma or fracture was caused nor was a device inserted into the bones of the animals before the inoculation. There were 2 studies where a fracture or a trauma was caused before the inoculation of the infection (Chadha *et al.*, 1999; Yoon *et al.*, 1999) and in

1 study a haematogenous infection in a bone implant was studied (Wang *et al.*, 2017c).

A haematogenous osteomyelitis model was developed to study the contribution of *S. aureus* Cna to the capacity of the bacteria to reach the bone from the bloodstream and cause an osteomyelitis (Elasri *et al.*, 2002). The authors infected NIH Swiss mice with a 100  $\mu\text{L}$  inoculum containing  $10^8$  CFU of *S. aureus* UAMS-1 or its isogenic Cna mutant strain UAMS-237 injected *via* the lateral tail vein. Their results showed that the mutation of Cna limited the capacity of *S. aureus* to cause osteomyelitis through the haematogenous route. Another study with a similar set up (150  $\mu\text{L}$  inoculum of  $10^6$  CFU of *S. aureus* ATCC 53657 injected in the lateral tail vein) described a biphasic development of the bacterial infection. There was an acute phase of infection in the tibiae during the first 2 weeks followed by a chronic phase until the termination at 60 d (Horst *et al.*, 2012).

Tuchscher *et al.* (2017) studied the role of *sigB* in the development of a chronic osteomyelitis infection. They used a mouse model based on studies by Horst *et al.* (2012) and infected the animals with 150  $\mu\text{L}$  of  $10^6$  CFUs *via* the lateral tail vein. Mice were infected with *S. aureus* LS1, *S. aureus* LS1 with *sigB* deleted and *S. aureus* LS1 *sigB*-deleted strain complemented for this deletion. Their results demonstrated the importance of *sigB* to establish osteomyelitis through the haematogenous route (Tuchscher *et al.*, 2017).

Wang *et al.* (2017c) developed a well-described model to mimic a haematogenous infection with an implanted device. They used male C57BL/6 mice and inoculated *S. aureus* SAP231 intravenously through the retro-orbital sinus 21 d after the implantation of a pin in the bone. All mice challenged with either  $10^6$  CFU or  $5 \times 10^6$  CFU inoculum survived the bacterial challenge. An inoculum of  $10^7$  CFU was too large and killed several animals. However, not all the inoculated mice developed the hematogenous implant infection because at 28 d post-inoculation there were no detectable CFU from the implants or surrounding tissues (Wang *et al.*, 2017c).

In general, bone haematogenous infection models were successfully developed in the mouse and allowed for studying the essential bacterial features to establish an acute or chronic bone infection.

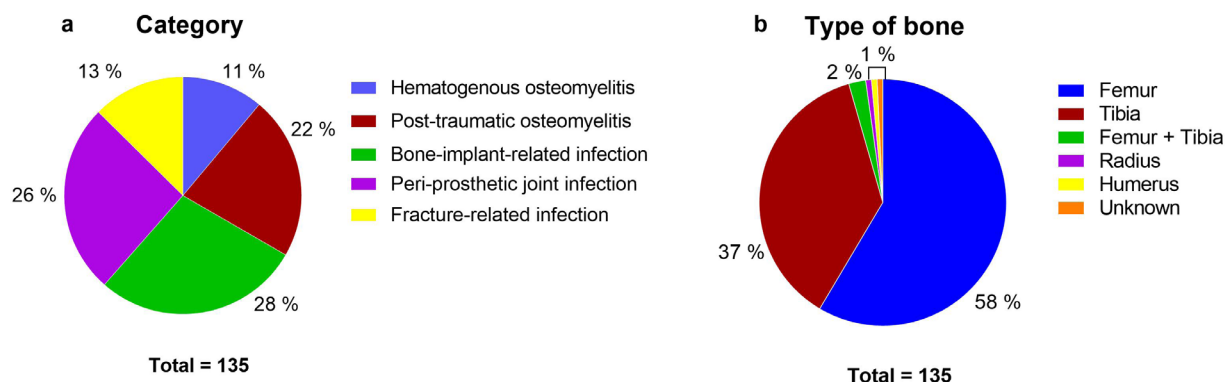

Fig. 5. Classification of the osteomyelitis mouse models by (a) categories and by (b) type of bone infected. 135 studies were included in the graphs.

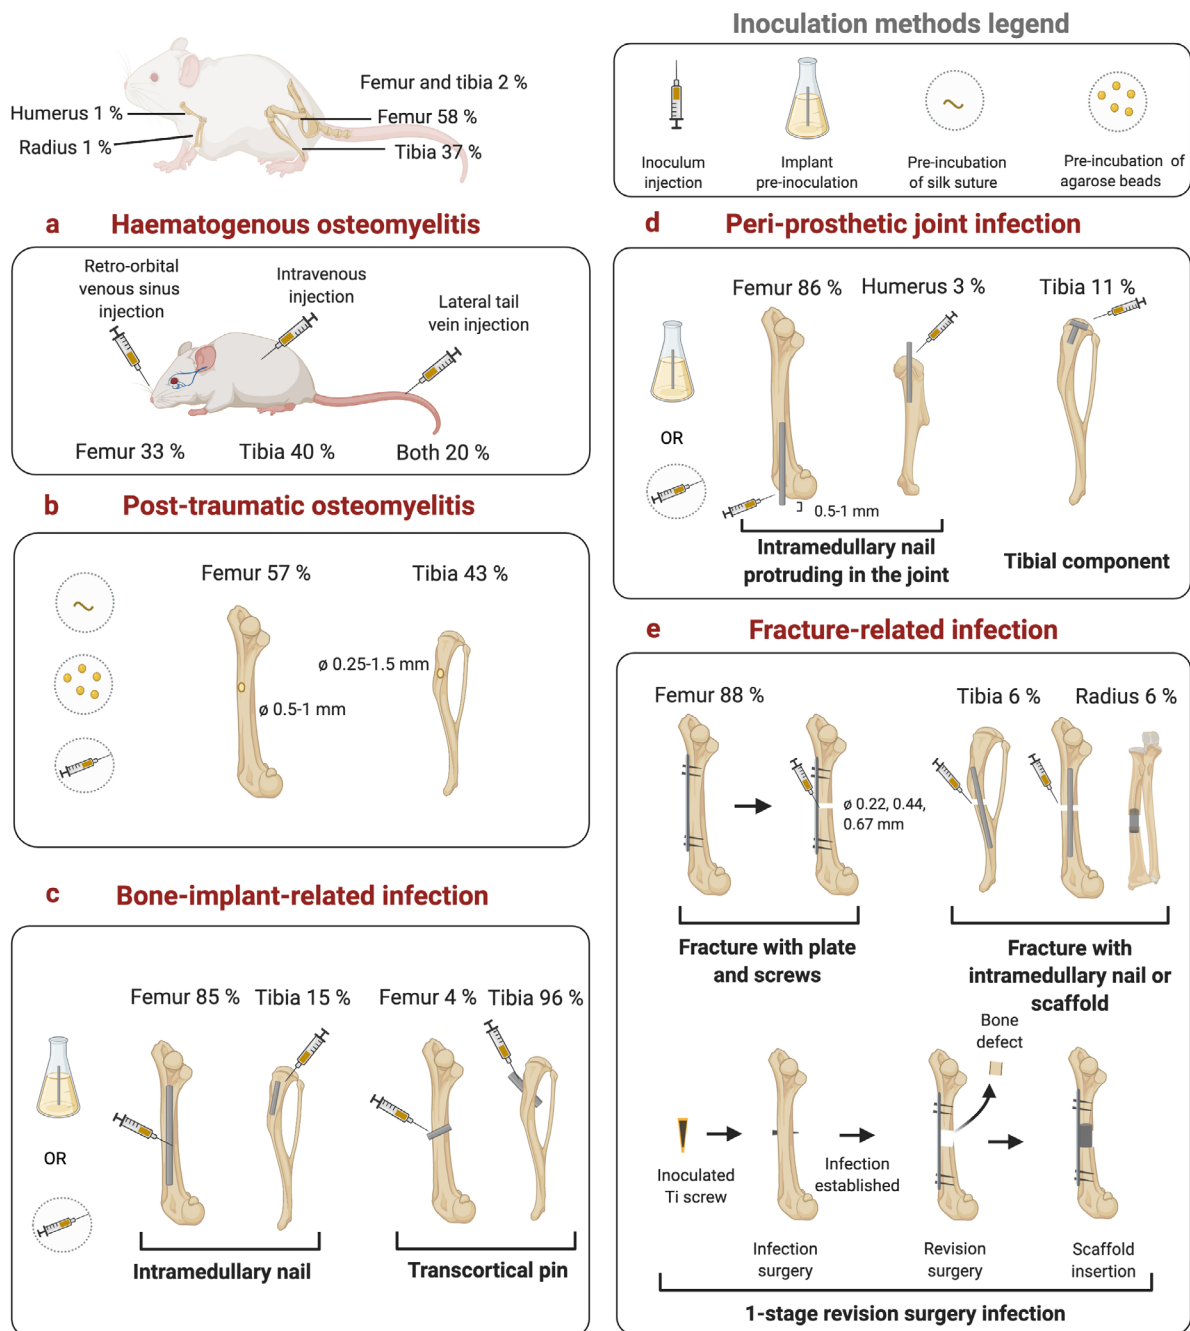

*Post-traumatic osteomyelitis mouse models*

Osteomyelitis can occur after trauma even without the insertion of a fixation device (Table 2; Fig. 6b). The incidence of osteomyelitis following open fractures is reported to be 1-30 %, depending significantly on the grade of trauma and the type of treatment administered (Metsemakers *et al.*, 2015).

The post-traumatic osteomyelitis studies that have been included in this review have in common the creation of a unicortical bone defect and the local infection of the defect with 0.5 to 2  $\mu\text{L}$  of bacterial inoculum containing  $10^5$  to  $10^8$  CFU as inoculum. Such a small volume of inoculum is recommended to prevent the diffusion of the inoculum to the

contiguous tissues and to better mimic the real situation occurring in patients. The unicortical defect was a perforation only affecting one lateral side of the bone, with a size that ranged from 0.5 to 1.5 mm of diameter (Table 2, Fig. 6b). In 57 % of the post-traumatic osteomyelitis studies the defect was created in the mouse femur and in 43 % in the tibia (Fig. 7b).

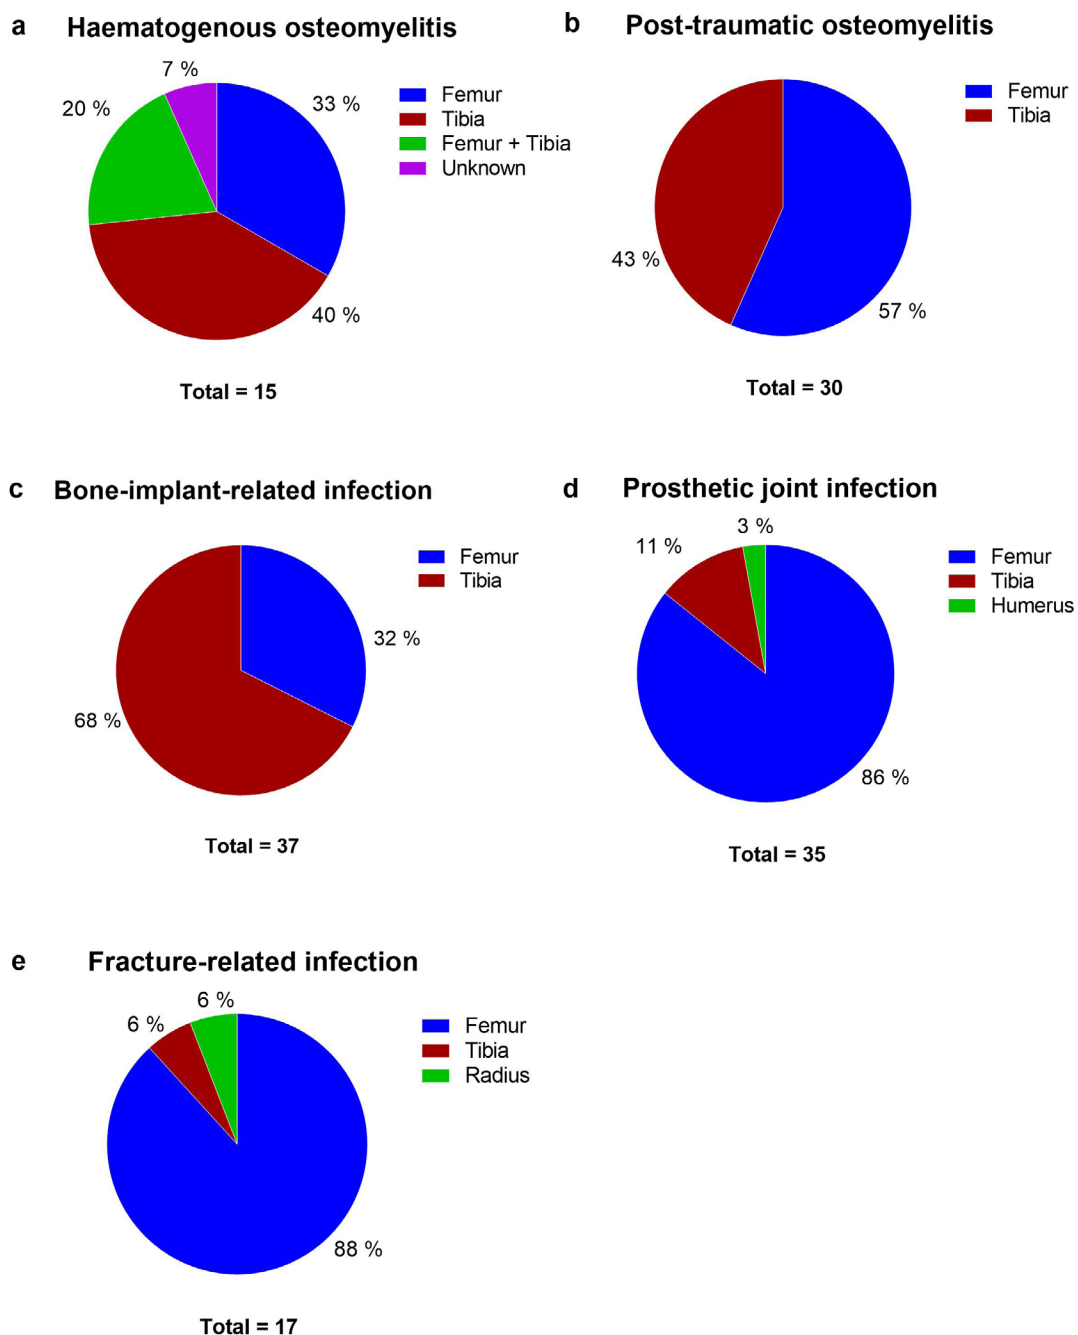

The post-traumatic osteomyelitis mouse models were used to study different virulence factors involved in the pathogenesis of the osteomyelitis as described previously (Cassat *et al.*, 2013; Isogai *et al.*, 2020; Loughran *et al.*, 2016; Wilde *et al.*, 2015; Xiao *et al.*, 2017). The models were also used to study the effects of the immune response in clearing

the infection and in the repair of the bone damage (Chen *et al.*, 2017; Marriott *et al.*, 2004; Putnam *et al.*, 2019; Wagner *et al.*, 2019; Yoshii *et al.*, 2002b). For example, Marriott *et al.* (2004; 2005) developed a trauma-induced staphylococcal osteomyelitis model to study the inflammatory response of osteoblasts to infection. They created a bone defect in the bone cortex, inoculated with  $10^3$  CFU of *S. aureus* UAMS-1 in agarose beads, and evaluated inflammatory mediators' levels for 4 d. An increase in the level of the cytokines IL-6 and MCP1 by the osteoblasts was measured in the animals infected with *S. aureus*. The positive recruitment of macrophages by the MCP1 to clear the infection also had the negative consequence

of an increased inflammation with bone damage (Marriott *et al.*, 2004; 2005). An increase in the levels of IL-6 was also observed in a study where a silk suture, pre-inoculated with  $10^5$  CFU of a clinical isolate of *S. aureus*, was inserted into the tibia of ICR mice (Yoshii *et al.*, 2002b). This resulted in a local elevated level of the cytokines IL-6 and IL-1 $\beta$  in the early phase of the infection related to the bone damage, which was followed by an increase in TNF $\alpha$  and IL-4 in a later phase of the infection (Yoshii *et al.*, 2002b). Putnam *et al.* (2019) studied the host immune pathways that contribute to bacterial immunity but also to bone destruction during *S. aureus* osteomyelitis. They created a bone defect in C5BL/6J wild type and

**Fig. 7. Type of bone infected (tibia, femur or both) in each category.** (a) Haematogenous osteomyelitis, (b) post-traumatic osteomyelitis, (c) bone-implant-related infection, (d) PJI, (e) fracture-related infection. 135 studies were included in the graphs.

in MyD88<sup>-/-</sup> and IL1r1<sup>-/-</sup> knock-out mice, infected them with a 2 µL inoculum containing 10<sup>6</sup> CFU of *S. aureus* AH1263 strain and measured cytokine levels after 14 d. They discovered an essential role of IL-1R to control the local bacterial replication during osteomyelitis and IL-1R contribution to bone destruction. Specifically, they demonstrated that there is an increase in the numbers of osteoclasts residing on the bone surface during the infection (Putnam *et al.*, 2019).

The post-traumatic osteomyelitis models were used to evaluate the efficacy of antimicrobial and anti-inflammatory strategies to prevent and treat both bone infection and inflammation (Funao *et al.*, 2012; Lu *et al.*, 2019; Takahashi *et al.*, 2008; Wagner *et al.*, 2016; Wu *et al.*, 2018; Zhu *et al.*, 2019). Funao *et al.* (2012) established a real-time, quantitative and reproducible osteomyelitis mouse model using the bioluminescent bacterial strain *S. aureus* Xen 29. They perforated the femur to simulate an osteotomy, injected a 1 µL inoculum containing 10<sup>8</sup> CFU in the medullar cavity and followed the infection *in vivo* (Funao *et al.*, 2012). Wagner *et al.* (2016) created a mouse model to analyse bone loss and regeneration following *S. aureus* bone infection and treatment. They inoculated C57BL/6 mice tibiae with 2 × 10<sup>3</sup> CFU of *S. aureus* Rosenbach 1884 and, after 14 d, performed debridement and applied antibiotic therapy. The treatment group showed complete eradication of the bacteria, whereas the infection persisted in the control group (Wagner *et al.*, 2016). Wu *et al.* (2018) used a post-traumatic osteomyelitis mouse model to evaluate the efficacy of the immune modulator baicalin to prevent bone destruction by regulating the toll-like receptor 2. They inoculated BALB/c male mice with 1 µL of 10<sup>8</sup> CFU of *S. aureus* ATCC 43300 with or without baicalin and showed that baicalin reduced the destruction of the bone (Wu *et al.*, 2018). Lu *et al.* (2019) developed a bone defect infection mouse model in ICR/JCL with 2 µL of 10<sup>6</sup> CFU of *S. aureus* ATCC 6538 to evaluate the efficacy of intravenous injection of the antibiotic gentamicin combined with a photodynamic therapy as a treatment for osteomyelitis (Lu *et al.*, 2019).

In conclusion, post-traumatic osteomyelitis mouse models can be used to elucidate the pathophysiology of the bone infection. They can be used to study the influence of the bacterial virulence factors or the influence of the infection in the immune system activation causing an increased bone damage.

#### *Bone-implant-related infection mouse models*

The presence of a foreign body, such as a bone implant, increases the risk of infection because the implant acts as a niche for bacterial colonisation and compromises the local immune response against the bacteria. An established bone-implant-related infection mouse model to study the pathophysiology of the bone implant infection is the intramedullary implant model (Table 3; Fig. 6c). This method basically consists of the implantation of a K-wire, a pin or a nail into the intramedullary canal of the

femur or tibia, combined with a bacterial inoculum (Table 3, Fig. 6c). Other studies have described the transcortical insertion of a pin into the femur or tibia that in some cases was bent at both ends to increase the device stability (Jørgensen *et al.*, 2014; Li *et al.*, 2008; Prabhakara *et al.*, 2011a). The bacterial inoculum was applied directly into the femoral or tibial insertion site to mimic a contamination during surgery (Funao *et al.*, 2016). Alternatively, the device was pre-inoculated before insertion into the bone to mimic the contamination of the device (Jørgensen *et al.*, 2014). In 68 % of the studies, the implant was inserted in the tibia of the animals and in 32 % in the femur (Fig. 7c). These bone-implant-related infection mouse models were used to study different pathophysiological mechanisms of osteomyelitis related to bone implants. For example, a recent study revealed that *S. aureus* bacteria can colonise very small spaces in the bone such as canaliculi and osteocyte lacunae of cortical bone, sites in the bone which are difficult for immune cells to reach (de Mesy Bentley *et al.*, 2017). These models were also applied to study different pathways and aspects of the immune response to the infection and the implant (Prabhakara *et al.*, 2011a; Prabhakara *et al.*, 2011b).

The models were also extensively used to evaluate the efficacy of antimicrobial compounds administered either systemically (Jørgensen *et al.*, 2016; Li *et al.*, 2008) or locally at the site of infection (Crane *et al.*, 2009; Funao *et al.*, 2016; Wells *et al.*, 2018; Zhang *et al.*, 2019a). Novel strategies for preventing or treating infection, such as passive immunisation (Varrone *et al.*, 2014), hyperbaric oxygen therapy (Jørgensen *et al.*, 2017; Shandley *et al.*, 2012) and antimicrobial peptides (Choe *et al.*, 2015), were also evaluated using these models.

In conclusion, the bone implant infection models allow for the study of the different interactions that occur between implant, infection and immune response in the bone environment and can be used to evaluate the efficacy of antimicrobials administered systemically or locally at the implant site. However, in these models there is no fracture nor device replacement to enable the study of the healing process in the presence of infection and implant. The fracture itself also influences the clearance of the infection. Hence, the model does not allow for studies on revision surgery with debridement and lavage or for evaluating antimicrobial devices used to treat infected bone tissue after removal of a contaminated device.

#### *Bone-implant-related infections in diabetic mouse models*

Diabetes is one of the most relevant risk factors in implant-related infection and its prevalence is growing worldwide (Berendt *et al.*, 2008). Diabetes is a disease in which high blood glucose levels occur. It can be due to a loss of the insulin-producing β-cells in the pancreas islets, known as T1D, or to insulin resistance due to a glucose-enriched diet, known as T2D (Farnsworth *et al.*, 2015). Both T1D

and T2D animal models are used to study diabetic complications, such as osteomyelitis, and their potential treatment.

Lovati *et al.* (2013) were the first to describe a diabetic bone-implant-related infection mouse model (Table 4). They compared the development of bone implant infection in the T1D diabetic mouse strain diabetic NOD/ShiLtJ and in non-diabetic CD1 mice (Lovati *et al.*, 2013). Their results showed that the same bacterial inoculum of  $10^3$  CFU of *S. aureus* ATCC 25923 induced bone-implant infection in the diabetic mice but not in the wild type mice. This animal model may be a useful tool for *in vivo* testing of treatment strategies in diabetic and non-diabetic individuals. Moreover, the authors showed the synergistic effects of the vasodilator PGE1 with an antibiotic, as a co-treatment for bone-implant infection in diabetic mice (Lovati *et al.*, 2014).

Farnsworth *et al.* (2015) studied the risk factors of orthopaedic infections for diabetic patients by comparing the development of bone implant infection and adaptative immunity in T1D and T2D male C57BL/6J mice. The T1D model was induced using a toxic agent that selectively destroys the beta pancreatic cells (*i.e.* streptozotocin) eliminating the insulin production. The T2D model consisted of 5 week old mice that received a high-fat diet (60 % kcal). To confirm the hyperglycaemia, the glucose levels were measured at several time points. Then, the investigators inserted a surgical wire into the tibia of the animals that had already been inoculated with *S. aureus* Xen 36. Results showed that T2D mice had a more severe *S. aureus* osteomyelitis than T1D mice (Farnsworth *et al.*, 2015).

#### PJI mouse models

PJI following total joint arthroplasty of the hip or knee, despite the low incidence of 1-2 %, is still associated with a large burden in orthopaedic surgery. The PJI mouse models' studies considered in the present review principally describe the insertion of a pin into the intramedullary canal that protrudes 0.5-1 mm into the joint (Table 5, Fig. 6d, Heim *et al.*, 2014; Heim *et al.*, 2015a; Kaur *et al.*, 2016; Thompson *et al.*, 2017; Thompson *et al.*, 2018). To better mimic the PJI, other studies have developed the tibial component of the knee prosthesis and press-fitted this into the tibia, exposed to the joint space (Carli *et al.*, 2017; Carli *et al.*, 2018; Hernandez *et al.*, 2019). In all the studies, the bacterial inoculum was pipetted or injected into the joint tissue or space to reproduce the principal clinical aetiology through intraoperative contamination (Table 5). 86 % of the studies inserted the device into the femur of the animals, 11 % into the tibia and 3 % into the humerus (Fig. 6d, 7d).

Bernthal *et al.* (2010) model provided real-time longitudinal tracking of the infection in a post-surgical joint for 10 d by using a bioluminescent *S. aureus* strain and monitoring the inflammation with the use of a mouse line that possesses fluorescent neutrophils, the LysEGFP knock-in mice. They

showed a more acute joint infection when the mice were inoculated with  $5 \times 10^3$  or  $5 \times 10^4$  CFU *versus* a mild infection, resembling a chronic infection, following challenge with a bacterial inoculum of  $5 \times 10^2$  CFU. Mice inoculated with 2  $\mu$ L containing either  $5 \times 10^3$  or  $5 \times 10^4$  CFU developed an increased bacterial bioluminescent signal corresponding to increased bacterial numbers and marked swelling of the affected leg within 3 d, consistent with an acute joint infection. In contrast, mice inoculated with  $5 \times 10^2$  CFU developed a low-grade infection, resembling more a chronic infection (Bernthal *et al.*, 2010). This model was further used to compare infection development and biofilm formation with different *S. aureus* strains (Pribaz *et al.*, 2012) or by extending the experiment to even 40-49 d to study a chronic infection (Niska *et al.*, 2012a; Pribaz *et al.*, 2012). Interestingly, the studies described a peak in bioluminescence for bacteria as well as neutrophils at 3 d, corresponding to the acute phase of the infection, and bioluminescence values decreasing over time, corresponding to the chronic phase of the infection. As previously mentioned, a decrease in luminescence does not necessarily correspond to a reduction in bacterial numbers but may well be associated with a lower metabolic activity of the bacteria in the later, chronic stages of infection (Pribaz *et al.*, 2012). To provide deeper tissue penetration, a photoacoustic imaging system was applied to monitor the infection in this type of mouse model (Wang *et al.*, 2017a). However, this method was only used to study a 4 d infection.

Sheppard *et al.* (2020) developed a mouse model with an implant in the humerus that was also protruding into the joint. The mouse humerus and femur have a similar diameter. In this model, two inoculum doses were evaluated: a lower inoculum of  $10^3$  CFU that caused mild osteolysis and a higher inoculum of  $10^4$  CFU that caused severe osteolysis and failure of the shoulder.

These models were also extensively used to evaluate the efficacy of antimicrobial compounds administered either systemically (Niska *et al.*, 2013) or locally at the site of infection (Bernthal *et al.*, 2010; Carli *et al.*, 2017; Stavrakis *et al.*, 2016; Stavrakis *et al.*, 2019; Thompson *et al.*, 2017). In a comparative study, local antibiotic administration was shown to be more efficacious than systemic administration (Young *et al.*, 2015).

In summary, the PJI mouse models described in this section can reproduce the environment of the clinical condition by either incorporating the prosthetic device into the joint or protruding into joint and inoculating the infection into the joint. However, the small size of the mouse hampers the development of all the parts of the prosthetic device that are used for PJI human patients.

#### Fracture-related infection mouse models

A bone fracture is usually fixed using an intramedullary nail or a fixation plate with bone

screws. The presence of an infection will compromise the immune response and the regeneration of the bone. The incidence of an infection after the fixation of a fracture ranges from 1 % in closed fractures to 30 % in complex open tibial fractures (Metsemakers *et al.*, 2015).

To mimic this clinical situation, fracture-related infection mouse models fix a fracture using a fixation plate or an intramedullary nail. In the studies that fix the fracture using a fixation plate and screws, the fixation plate is applied to the long bone with screws, followed by fracture or removal of a part of the bone and challenge with a bacterial inoculum (Table 6, Fig. 6e). All the studies using fixation plates apply surgical devices such as the “MouseFix” plate with 4 or 6 screw holes and/or surgical tools such as a Gigli saw to create a fracture size diameter of 0.22, 0.44 or 0.67 mm (RISystem, Davos, Switzerland). Alternatively, the studies that fix the fracture using an intramedullary nail, create the fracture first and then ream the bone pieces using a nail (Cahill *et al.*, 2021; Johnson *et al.*, 2018). 88 % of the studies analysed created the bone fracture in the femur, 6 % in the tibia and 6 % in the radius (Fig. 6e, 7e).

Rochford *et al.* (2016) used this type of model to study the immune response during healing in the presence of an infection. They pre-inoculated the fixation device, 20 min before surgery, with  $10^5$  CFU/implant of *S. aureus* JAR 06.01.31. Sabaté-Bresco *et al.* (2017) used the same model and showed that stable fracture fixation led to better clearance of infection than unstable fixation. Moreover, the osteotomy gap had healed in the animals with the stable fixation by 30 d post-surgery (Sabaté Bresco *et al.*, 2017).

In clinical practice, depending on the infection severity, there are different surgical approaches to treat an infection, such as one-stage or two-stage revision. A one-stage revision consists of one surgical intervention, with implant retraction, debridement and implantation of a new prosthesis. A two-stage revision consists of two surgical interventions: implant retraction, debridement and wound closure in the first stage surgery and, after several weeks, implantation of a new, cemented prosthesis during the second stage surgery. Moreover, a two-stage revision can also consist of implant removal with debridement and application of local antibiotics (spacers/beads) in the first stage and implant placement with antibiotic-loaded bone cement in the second stage.

Different parts of these revision-surgery approaches were mimicked in osteomyelitis mouse studies. For instance, the stage of revision surgery due to infection in the bone fracture fixation infection mouse model was first introduced by Windolf *et al.* (2013; 2014). The authors created a bone fracture fixation mouse model, with lavage and debridement of the infection at 7 and 14 d post-implantation and infection (Windolf *et al.*, 2013). In a later study, they used this model to evaluate the treatment efficacy of a PMMA plate coated with the metallo-endopeptidase

lysostaphin to prevent *S. aureus* infection (Windolf *et al.*, 2014). The model was also used by others to evaluate the efficacy of other antimicrobial materials such as a calcium sulphate with gentamicin bone filler (Oezel *et al.*, 2019) or hyperbaric oxygen therapy (Büren *et al.*, 2019).

Other authors have developed models with hardware exchange to mimic one-stage revision surgery. For example, Inzana *et al.* (2015b) established a mid-diaphyseal femoral osteotomy repaired using a fixation device that was pre-inoculated with a collagen sheet containing *S. aureus* to initiate the infection. At 7 d post-infection, revision surgery with debridement and placement of an antibiotic-laden spacer was performed and, at 28 d post-infection, the efficacy of this procedure was evaluated. Yokogawa *et al.* (2018) established a similar model to investigate the synergy between systemic vancomycin treatment with immunotherapy. They pre-inoculated a bone screw with *S. aureus* and inserted it into the middle of the femur shaft to establish an infection.

Trombetta *et al.* (2019a) compared one- and two-stage revision surgery using a more complex *in vivo* model that more closely resembles the clinical situation. They pre-inoculated a bone screw with *S. aureus* Xen 36 and placed it in the middle of the femur for 7 d to establish an infection. Then, they removed the infected hardware and introduced a fixation device and a PMMA spacer with or without local antibiotic delivery. The delayed treatment of the infection, described in the studies above, is a relevant clinical feature that increases the challenge of efficient bacterial clearance.

Regarding the healing of the fracture, several authors have shown – using X-ray or  $\mu$ CT – a complete bone regeneration in the non-infected group when compared to an infected group of animals (Sabaté Bresco *et al.*, 2017; Windolf *et al.*, 2013; Windolf *et al.*, 2014). Moreover, the bone healing was also observed after 28 d post-osteotomy in the treatment group infected (Windolf *et al.*, 2014). Thus, the evaluation of bone healing indicates the progress in the eradication of the infection and osteomyelitis.

To summarise, fracture-related infection models allow the creation of procedures to study a wide spectrum of clinical situations and can be used to study new strategies for the prevention and treatment of osteomyelitis related to orthopaedic bone fixation devices.

### Advantages, limitations and conclusions

The advantages of the osteomyelitis mouse models are the similarity of their bone physiology to that of humans, their relatively low cost, the availability of well-defined inbred strains and molecular and immunological tools as well as the possibility of genetically modifying them.

Mouse models have proven to be adaptable to specific desired model conditions, evolving

from simpler models, such as the post-traumatic osteomyelitis (Funao *et al.*, 2012), through the bone-implant infections (Li *et al.*, 2008), until more complex models such as the fracture-related infection with hardware exchange (Trombetta *et al.*, 2019a; Yokogawa *et al.*, 2018). Thus, these *in vivo* mouse models can be applied to study a variety of research questions related to osteomyelitis infection.

Larger animal models such as rabbits, dogs or sheep show more similarities to humans than mouse in their bone microstructure, macrostructure and bone remodelling process (Muschler *et al.*, 2010; Pearce *et al.*, 2007; Wancket, 2015) and allow the use of implants of a size more closely resembling the actual implants used for humans. Moreover, larger animals such as dogs can tolerate multiple surgical procedures, allowing researchers to study some of the more complex procedures that are performed in humans (Patel *et al.*, 2009). However, larger animals are more expensive, as is their maintenance, and they take longer to reach skeletal maturity than mice (Patel *et al.*, 2009; Pearce *et al.*, 2007).

The use of GM mouse strains and molecular tools allows performing detailed studies on pathways and cells involved in the different mechanisms and processes of a disease, such as the inflammatory response to infections and fractures as well as the healing process. For example, Bernthal *et al.* (2014) used a GM mouse strain with fluorescent neutrophils to follow *in vivo* the inflammatory response to the infection and the presence of the implant. GM mice were also very useful for creating an osteomyelitis diabetic mouse model (Farnsworth *et al.*, 2015). Compared to larger animals, a wide range of mice GM lines is available, permitting the study of different aspects of osteomyelitis (Pearce *et al.*, 2007).

Mouse models are also relevant to developing new preventive and treatment strategies to control infections. For example, antimicrobial devices might be a promising approach to reduce infections in orthopaedic surgery. Coatings of implants used for fracture stabilisation in rats or mice are less expensive than those used in large animals such as sheep or goats. In fact, many authors have well-described procedures to test the efficacy of antimicrobial coatings in osteomyelitis mouse models (Table 3-6). Such models can be used as a first step in the *in vivo* evaluation of *in vitro* results, to study the distribution of drugs in bones and other organs and to develop new antimicrobials for infection prevention. If the aim of using an antimicrobial device is to prevent an infection, it will be necessary to evaluate its *in vivo* antimicrobial efficacy for at least the first 10 d. But, if the antimicrobial device is meant to be used as a treatment, a longer evaluation will be necessary (Moriarty *et al.*, 2019). In any case, an antimicrobial orthopaedic device must prove its antimicrobial efficacy against relevant Gram-positive and Gram-negative pathogens (such as multidrug-resistant bacteria), drug release, lack of inducing excessive inflammatory responses, prevention of

bone tissue damage and support of bone healing. The antimicrobial efficacy should be determined by quantification of CFUs on the implant as well as in the bone tissue and surrounding soft tissue at relevant time points. Moreover, the inflammatory response to the device can be determined by measuring the cytokines in the tissue and performing immunohistology. Destruction of the bone tissue can be evaluated using imaging techniques such as  $\mu$ CT or MRI.

Most of the studies analysed established an infection using *S. aureus* clinical strains because *S. aureus* is one of the major osteomyelitis pathogens (Fig. 3a). However, it is also relevant to study more in depth the pathophysiology of other devastating bacterial and fungal species related to those that cause osteomyelitis – such as coagulase-negative staphylococcal and streptococcal species, *P. aeruginosa*, *C. acnes*, *A. baumannii*, *C. albicans* – or polymicrobial infections (Bemer *et al.*, 2014; Kavanagh *et al.*, 2018).

The mortality rate related to these osteomyelitis mouse models varied between studies principally due to the differences in the infective dose, the virulence of the bacterial strain and the type of surgical procedure. Part of the information related to the mortality rates was retrieved from the publications and another part by consulting the authors of studies where no details on mortality were published.

The type of inoculum administration and the infectious dose applied in the animals will directly affect the animal mortality rate. For example, the administration of a localised low inoculum is not expected to cause an invasive spread of the infection (Lloyd Miller, personal communication, 2021). However, if a high infective dose is locally inoculated into the joint or bone, it could cause an invasive haematogenous spread leading to sepsis and, consequently, to the death of the animals (Lloyd Miller, personal communication, 2021). Therefore, it is important to include dose-determining studies to find the proper inoculum to administer to the animals, depending on the final aim of the study.

The haematogenous models with associated sepsis had a high mortality rate of 20-50 % due to the highly infective doses administered that lead to the development of sepsis, infection of other organs or extreme weight loss that necessitated euthanasia (Horst *et al.*, 2012; Lorena Tuchscher, personal communication, 2021). The risk of sepsis development was also affected by the virulence of the bacterial strain used and the susceptibility of the mouse strain infected (Lorena Tuchscher, personal communication, 2021). In the haematogenous implant study, 3 different bacterial inocula were used ( $10^5$  to  $10^7$  CFU), where only the largest bacterial inoculum caused a mortality rate of 10 % (Wang *et al.*, 2017c).

The post-traumatic infection model, the bone implant infection model and the PJI model in some studies had a mortality rate ranging from 1 to 10 % due to anaesthesia complications during the surgical

procedure (Ford *et al.*, 2020, Hernandez *et al.*, 2019; Elysia Masters, personal communication, 2021; Tammy Kielian, personal communication, 2021). Other studies did not report any loss of animals with these types of mouse models (Alexandra Stavrakis, personal communication, 2021). In some studies, there was a range of animals used per group “such as 5-8 animals per group” (Ashbaugh *et al.*, 2016), which was related to the numbers of animals available to undergo the surgical procedure on different days and not to the mortality rate (Lloyd Miller, personal communication, 2021).

The studies that used fracture-related infection models encountered more complications. In the models with a fracture and an intramedullary nail the mortality was ranging between 5 and 10 % and it was related to surgical complications (Cahill *et al.*, 2021; Andres García, personal communication, 2021). In the models with a fracture fixed using a fixation plate, the mortality was related to intraoperative complications (ranging between 2 and 29 %) such as implant misplacement (Sabaté Brescó *et al.*, 2017), anaesthesia fatality (Oezel *et al.*, 2019; Sabaté Brescó *et al.*, 2017; Ceylan Windolf, personal communication, 2021; Fintan Moriarty, personal communication, 2021) or cardiopulmonary instability (Oezel *et al.*, 2019). The fatalities were also related to post-operative complications such as fixation device failure (Oezel *et al.*, 2019; Sabaté Brescó *et al.*, 2017; Ceylan Windolf, personal communication, 2021), fracture of the bone (Fintan Moriarty, personal communication, 2021), secondary infections (Sabaté Brescó *et al.*, 2017) or device failure during revision surgery (Trombetta *et al.*, 2019b). On the other hand, several other studies did not have any losses of animals (Büren *et al.*, 2019; Inzana *et al.*, 2015a; Inzana *et al.*, 2015b).

Several authors concurred that once the surgical procedure and the infective dose were well-established and the personnel well trained, the mortality encountered was predominately related to the anaesthetics used during the procedure.

Other important features to study in more detail are the bacterial virulence factors related to the disease including the bacterial immune evasion mechanisms to avoid the clearance of the pathogens. The role of the immune response in osteomyelitis is very relevant for future studies considering the importance of the macrophages and neutrophils in the clearance of the infection and in the regeneration of the bone tissue. Understanding the cellular and molecular pathways involved in the recruitment, differentiation and activation of monocytes seems to be a central axis of research in the osteo-immunomodulation response. The mouse models can also be used to investigate how antimicrobial and anti-inflammatory drugs should be applied to the bone to prevent or treat the infection and orchestrate the inflammatory response to enhance the regeneration of the bone tissue.

Additional types of clinical osteomyelitis could also be mimicked using mouse models. For example, Röntgen *et al.* (2010) developed an external fracture

fixation mouse model without infection. An infection could be established in this model to study its influence on bone healing with this type of fracture fixation device. Another clinical osteomyelitis model that could be established is the two-stages exchange of contaminated internal fixation hardware. However, the small size of the mouse makes it more challenging to perform multiple surgical procedures. Another interesting aspect for further study is the influence of the microbiome in the predisposition to osteomyelitis and how *e.g.* probiotics could help to reduce the effects of the disease (Hernandez *et al.*, 2019). A bone infection could also be merged with other clinical models to try to reproduce models closer to the patient situation. For instance, Zhang *et al.* (2019b) developed a mouse fracture model using 20 to 28 months old mice presenting a *P. aeruginosa* infection in the endotracheal tube. This mimics a hospital-acquired infection due to the endotracheal tube, as occasionally present in patients with a fracture. The next step would be to inoculate the endotracheal tube to cause sepsis and study the ability of pathogens such as *S. aureus* to infect a bone fracture and how to prevent it using prophylaxis. However, it can be foreseen that establishing such a challenging model will be difficult.

The standardisation of the models is highly relevant for study results to be reproducible and comparable between laboratories and to achieve a better translation to the clinic (Coenye *et al.*, 2018; Muschler *et al.*, 2010). Ideally, standardised models would need to be developed but the wide variety of conditions used in the different models (as described in the present review) indicate that standardisation may be difficult. To allow for full understanding of differences between studies, it is vital to provide very clear and detailed descriptions of the models. For instance, the mouse strain used, animal age, gender, and weight should always be reported. The use of a well-defined bacterial strain, inoculum volume and dose as well as method of administration is also important. In this respect, guidelines defining the minimum study information that needs to be reported would be very useful tools to achieve these goals (Allkja *et al.*, 2020; Moriarty *et al.*, 2019).

In conclusion, the mouse is an excellent first step *in vivo* model to study the pathogenesis, inflammation and healing process of osteomyelitis with or without implanted medical devices and to evaluate novel prophylaxis and treatment strategies.

## Discussion with Reviewer

**Reviewer:** There is apparently a wide range of mouse models available. Would the field benefit from standardisation and a reduction to relatively fewer models allowing greater consistency? What may be the pros and cons of this approach?

**Authors:** This is a very good point to discuss. Indeed, in each osteomyelitis section, the infection has been performed differently and by using a different mouse line, age and gender, different bacterial strain, infectious dose and volume or different evaluation methods. All these variables need to be taken into consideration when the studies are compared. Standardisation could be applied both for *in vitro* and *in vivo* assays and would increase the reproducibility of studies between laboratories. Moreover, the

standardisation of the model and the evaluation methods could be used as a preclinical step to follow to evaluate the efficacy of antimicrobial preventive or treatment strategies (Coenye *et al.*, 2018). However, since there simply is a vast number of relevant clinical parameters that vary from study to study, in many cases, models will need to be tailored to the specific

clinical situation. Then, to assess comparability of the models and study outcomes, minimum information guidelines are advised.

**Editor's note:** The Scientific Editor responsible for this paper was Fintan Moriarty.
